GRAVIMETER Gs 12

is an instrument of the type Gs 11, which additionally is equipped with a set of calibrated weights. By these weights (i. e. 19 balls) a difference in gravity of about 2,000 mgals can be compensated and measured. This can be done for any multiple of 100 mgals directly. Intermediate values are determined as before by means of a fine measuring spring.

TORSION MAGNETOMETER Gfz

is a new Askania-Magnetometer of high quality. Here are the data:

Range: 65,000 γ
Sensitiveness: 25 γ / s. d.
Reading accuracy: ≤ 0.1 s. d.
Weight: 3 kg (6.6 lb.)

Temperature compensated and independent of the azimuth.

Tripod for rough and final levelling.

And the result of all these advantages:

One measurement takes 40 seconds only!

Write for detailed specifications and additional information on these latest developments and on other Geophysical Instruments for Prospecting and Scientific Research.

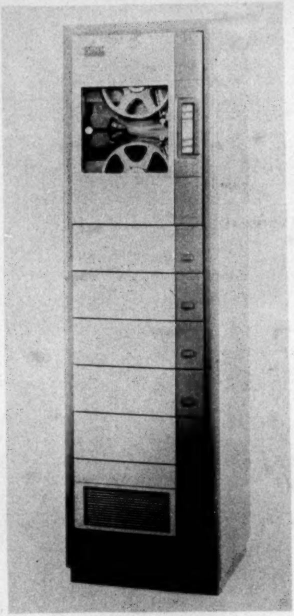
AMPEX PRESENTS THE *modular* FR-100



a versatile
new approach
to the
recording and reproduction
of data
on magnetic tape

From the pioneer and leader in magnetic tape instrumentation comes an all-new series of equipment. Every component of the Ampex FR-100 is designed as an interchangeable module. This provides an unlimited versatility for recording and reproducing complex combinations of data in the range from D.C. to 100,000 cycles. It reduces most line maintenance to a simple plug-in of spare components. And it forestalls future obsolescence by permitting adaptation to any conceivable changes in tape recording standards.

FEATURES

- Plug-in interchangeable amplifiers permit quick selection of Direct, FM or PWM recording or reproduction on any track.
- New precision head assemblies provide greater timing accuracy between tracks and compatibility with all of the interchangeable amplifiers.
- Recording and reproduction characteristics permit interchange of tapes with Ampex 300 and 800 series machines.
- Models available with from one to 14 tracks.
- Tape transport handles the six standard tape speeds from 1⅞ to 60 in/sec; other combinations on special order.
- A new Ampex standard of performance excells the widely accepted Ampex standards of the past.
- Construction throughout conforms with Mil spec. E-4158-A.

WILEY BOOKS

Recent and forthcoming titles of interest . . .

PRINCIPLES OF STRATIGRAPHY

By CARL O. DUNBAR *and* JOHN RODGERS, *both of Yale University.* Provides the first broad survey of stratigraphy in almost fifty years. Written from the viewpoint of basic principles, this book is illustrated by many examples from the stratigraphic record. The authors begin with a discussion of the environments of deposition, followed by a treatment of basic stratigraphic relations. They then describe the interpretation of specific lithotopes, and devote the final portion of the book to synthesis. The wealth of maps, cross-sections, and photographs is especially noteworthy. *Ready in June. Approx. 600 pages. Prob. $10.00.*

GLACIAL AND PLEISTOCENE GEOLOGY

By RICHARD FOSTER FLINT, *Yale University.* Based on the author's *Glacial Geology and the Pleistocene Epoch,* this entirely new book reflects the unprecedented advances in Pleistocene research during recent years. It presents a new treatment of glaciology, designed to be more meaningful in glacial geology. There are up-to-date discussions of sea-floor stratigraphy, soils, frozen-ground phenomena, and geochemical contributions to chronology and the measurement of temperatures. This work also features a more detailed consideration of animals and plants than was available in the earlier book. A great deal of new stratigraphic information is assembled in the form of correlation charts. *1957. In Press.*

PETROGRAPHIC MODAL ANALYSIS

By FELIX CHAYES, *Carnegie Institution of Washington.* Shows how to determine the relative amounts of minerals in a given rock by micrometric areal analysis. It is the only book sufficiently comprehensive to enable you to decide when and how to use the technique in your own research. Although based on statistics, it is written so that the reader does not have to be familiar with statistics to make use of its major results. Geologists, minerologists, and everyone working in the field will find this a valuable reference and guide. *1956. 113 pages. $5.50.*

PROPERTIES OF PETROLEUM RESERVOIR FLUIDS

By EMIL BURCIK, *The Pennsylvania State University.* Treats in a logical sequence the fundamental concepts on which petroleum engineering is based in so far as reservoir fluids are concerned. The book describes the hydrocarbons which constitute petroleum, the behavior of hydrocarbons in the gaseous state for ideal and for non-ideal systems, liquid systems and the properties of systems which contain both liquid and vapor, and the properties of crude oils and the empirical correlations which must be employed in working with systems of this type. Gives all necessary information to solve a wide variety of problems. *1957. 190 pages. $7.50.*

150 YEARS OF PUBLISHING

JOHN WILEY & SONS, Inc., 440-4th Avenue, New York 16, N. Y.

Preface

This list of members, corrected for changes received by March 10, 1957, supplants the list of November 10, 1954, published as Part 2 of the Transactions of December 1954. Following the alphabetical lists of individual and corporation members is a geographical list, by cities and states or territories for the United States and possessions, by cities in Canada, and by countries otherwise. A third portion is a list of the Committees of AGU and its Sections, which in turn is followed by a list of publications of AGU.

In the main alphabetical and the geographical lists, the code letters following the names are the usual ones for the Section affiliations, as follows:

(a) Geodesy
(b) Seismology
(c) Meteorology
(d) Terrestrial Magnetism and Electricity
(e) Oceanography
(f) Volcanology, Geochemistry, and Petrology
(g) Hydrology
(h) Tectonophysics

Geophysics in its broad aspects is taking an increasingly important position with respect to science as a whole, and its importance to our national welfare and the welfare of the world as a whole is being increasingly recognized. The postwar General Assemblies of the International Union of Geodesy and Geophysics--the Eighth in Oslo in 1948, the Ninth in Brussels in 1951, and the Tenth in Rome in 1954--have shown the trend. The attendance at the General Assembly in 1954 was almost double that of 1948.

Recognition is also indicated by the development of the International Geophysical Year, 1957-1958, in which over 40 nations are participating, with activity in this concerted effort covering the most remote parts of the Earth, with concentrated effort in the Antarctic, and with observation points on isolated islands of the Pacific and in tropical regions. Few geophysical data are now available from many of these areas.

There are many well-qualified workers in geophysics who are not now members of AGU and who should be members in order that AGU may be of greatest usefulness. It is to the advantage and benefit of the present members if these are brought into membership. Please do what you can to bring in at least one new member. This directory, especially the geographical section, should be of help in determining whom to approach. We invite each member to consider himself a member of a Committee of Five Thousand to secure 5000 new members. Please do your utmost in this matter in order that AGU may be of maximum service to you, that it may grow and more nearly fulfill its aims with respect to the broad field of geophysics, science as a whole, and the welfare of Man. To facilitate this, an application form has been inserted at the end of this directory.

Outstanding New McGRAW-HILL *Books*

WEATHER ANALYSIS AND FORECASTING—*New Second Edition*

Volume I. MOTION AND MOTION SYSTEMS—446 pages, $8.50
Volume II. WEATHER AND WEATHER SYSTEMS—284 pages, $6

By Sverre Pettersen, University of Chicago.

A complete revision replacing the original single volume because of the vast increase in new observational data from the upper atmosphere and the developments in the atmospheric motion theories. VOLUME I deals with the *dynamics* of atmospheric processes—cyclones, anti-cyclones, fronts, upper waves, etc., discussing in detail a number of special forecasting procedures illustrated by numerous examples. VOLUME II deals with *weather*, putting the emphasis on the thermodynamics of atmospheric processes—the theory of air masses, precipitation, thunderstorms, tornadoes, fog, and the prediction of weather. It is the *only* book to cover weather analysis and forecasting.

ELASTIC WAVES IN LAYERED MEDIA: With Geological Acoustical and Engineering Applications

By W. Maurice Ewing, Columbia University; W. S. Jardetzky, Columbia University, and Frank Press, California Institute of Technology. *McGraw-Hill Series in the Geological Sciences.* 375 pages, $10.00

A graduate level book of vital importance in geophysical prospecting, seismology, oceanography, etc. It is an outgrowth of a plan to make a uniform presentation of investigations on earthquake seismology, underwater sound, and model seismology. Wave propagation in layered media is of importance for geophysical prospecting, acoustical problems and seismology. Each subject begins with elementary discussion and culminates with advanced treatment.

ISOTOPE GEOLOGY

By Kalervo Rankama, University of Helsinki. 550 pages. $12.00

Here is a book of great interest to practicing geologists, geophysicists, and geochemists, and to the oil and mining industries in general. It shows how the isotopic constitution of the elements is used to determine the age of rocks and minerals, and how the energy released from radioactive processes relates to the history of the earth's crust. The subject finds applications in tracing oil and gas bearing formations and other mineral deposits of economic importance.

PHYSICS AND CHEMISTY OF THE EARTH—*Volume I*

By L. H. Ahrens, Oxford University; Kalervo Rankama, University of Helsinki, and S. K. Runcorn, Kings College, Newcastle. 326 pages, $8.00

In this first volume of a series of timely importance, a number of internationally known authorities present papers of great interest to geologists, geophysicists and geochemists. It provides authoritative and up-to-date surveys of progress and acquaints the geologist with the results and methods of geophysics and geochemistry. Included is a progress review on the geochemistry of the halogen group of elements and a review of some aspects of Russian geochemistry and geophysics during the last five years. It is particularly timely in view of the International Geophysical Year (1957-58) involving the large-scale cooperation of many nations.

MARK IV WEATHER STATION

PORTABLE • AUTOMATIC • RECORDING

Provides a continuous record on a special wide strip chart of:

1. **Air Temperature**
2. **Ground Temperature**
3. **Chill Factor**
4. **Solar Radiation**
5. **Barometric Pressure**
6. **Relative Humidity**
7. **Precipitation**
8. **Wind Flow**
9. **Wind Direction**

Completely self-contained. Packed size 22x36x7 inches. Weight only 60 pounds. Easily erected by one man in 10-15 minutes. Operates one week without attention. No external power required. Operates 130° to —70°F. Special 10-pen recording system and chart transport. Contains ink and chart paper supply adequate for over five months' operation.

Used extensively in U. S. Army and Air Force field tests to automatically record weather data. Supplied with shipping crate and shields for portable protection. Price $5,400.00. Further details supplied on request.

ARCTIC RESEARCH, Inc. Clare, Michigan

Research in ATMOSPHERIC PHYSICS

- Laboratory, Field, and Theoretical Studies
- RADAR Weather Studies
- AIRCRAFT for air sampling, etc.
- Quantitative PHOTOGRAPHIC ANALYSIS

POCKET ENCYCLOPEDIA OF ATOMIC ENERGY By FRANK GAYNOR

More than 2,000 entries defining and explaining concepts and terms in nuclear physics and atomic energy make this volume a vital handbook for all those concerned with atomic science. *Illustrations, charts, tables* $7.50

PLANT PHYSIOLOGY By MEIRION THOMAS

Professor of Botany, King's College, University of Durham

A general exhaustive survey of the field. Fourth completely revised edition. *Illustrated* $12.00

GEOGRAPHY IN THE TWENTIETH CENTURY By GRIFFITH TAYLOR

Twenty specialists explore the growth, fields, techniques, aims, and trends of modern geography. *Glossary and more than 50 text figures* $8.75

WATER By SIR CYRIL S. FOX

It is the intention of this volume to provide the reader with an outline of the Science of Water, both in the academic and practical aspects of the subject and to include details regarding its characteristics, its occurrence and its utilization. *Illustrated* $8.75

NUCLEAR PHYSICS By WERNER HEISENBERG

This new work, by one of the outstanding physicists of our time, treats of the development of atomic theory till the close of the nineteenth century. *With 18 half-tone illustrations and 32 line illustrations* $4.75

ELECTRONS, ATOMS, METALS AND ALLOYS By WILLIAM HUME-ROTHERY

An introduction to atomic theory with special reference to metals and alloys. The subject matter is presented in the form of a dialogue between an Older Metallurgist and a Younger Scientist, bringing out clearly the contrast between the old and new viewpoints. Revised edition. The author is Lecturer in Metallurgical Chemistry, University of Oxford. *171 Illustrations* $10.00

AETHER AND ELECTRICITY By SIR EDMUND WHITTAKER

The first exhaustive history of the classical and modern theories of aether and electricity. Set of two volumes. $17.50

AN ENCYCLOPEDIA OF THE IRON & STEEL INDUSTRY By A. K. OSBORNE

The purpose of this Encyclopedia is to provide a concise description of the materials, plant, tools and processes used in the Iron and Steel Industry, and in those industries closely allied to it, from the preparation of the ore, down to the finished product; and to define the technical terms employed.

The book is intended as a work of reference, not in any sense as a textbook; but the specialist might usefully look to it for information on subjects bordering his own. $25.00

COAL MINING By I. C. F. STATHAM

Throughout the whole book emphasis has been laid on the practical nature of the work which the entrant will need. As far as possible mathematical problems have been rigorously excluded and have been replaced by careful descriptive passages incorporating the basic theory and illustrating the practical applications of the theory. $15.00

GENERAL PRINCIPLES OF GEOLOGY By J. F. KIRKALDY

It is intended both as a general introduction to the subject and also as a starting point for specialized work on more limited aspects. *11 Tables, 84 line diagrams, 6 plates.* $10.00

SOIL WARMING BY ELECTRICITY By R. H. COOMBES

This book provides full information on the installation of soil warming equipment for greenhouse, cold-frame and cloche and includes a section on the financial aspect. $4.75

ELECTRICITY AND MAGNETISM By J. NEWTON

A detailed study of the phenomena and theory of electricity and magnetism. The first ten chapters set out clearly the fundamental material on current electricity. The author then deals with electrostatics, magnetic properties of materials, magnetometry and thermo-electricity, concluding with a survey system of units, electronic circuits and elementary atomic physics. The author is Senior Lecturer in Physics, at Northampton Polytechnic, London. $10.00

THE PETROLEUM REFINERY ENGINEER'S HANDBOOK By J. F. STRACHAN

The correlation of inspection procedure, methods, recording and equipment. *Numerous diagrams; 24 plates* $15.00

THE GENERATION OF ELECTRICITY BY WIND POWER By E. W. GOLDING

The book deals with the important matter of wind surveys for the choice of suitable sites, with the structure and behavior of the wind and with techniques for measuring it; also the economy of wind power. This book is of interest to all concerned with the provision of electric power. $12.00

ANTARCTICA IN THE INTERNATIONAL GEOPHYSICAL YEAR

(Geophysical Monograph No. 1 of the American Geophysical Union; Publication No. 462 of National Academy of Sciences—National Research Council.)

This book, just published, is based on a Symposium on the Antarctic held in Washington, D.C., in April, 1956. It comprises about 140 pages, is illustrated, and includes 16 papers by authorities on the Antarctic, with Introduction by L. M. Gould. Also included is a 42 in. by 42 in. map of the Antarctic compiled from the latest information for use in the current Antarctic planning.

Aspects covered include the following: Geographic and Meteorological, Geological and Structural (including Petrology), Upper Atmospheric Physics, Flora and Fauna, and the general program of the U.S. National Committee of IGY in the Antarctic.

The authors are: William E. Davies, Carl E. Eklund, Maurice Ewing, Bruce C. Heezen, E. O. Hulburt, Joseph Kaplan, George A. Llano, Finn Ronne, John Roscoe, Morton J. Rubin, A. H. Shapley, J. A. Simpson, Paul A. Siple, Robert P. Sharp, Duncan Stewart, E. H. Vestine, and H. Wexler.

PRICE $6.00

YOST, Dr. W. Jacque, Ohio Oil Co., 539 S. Main St., Findlay, Ohio (bd) 51

YOUMANS, Mr. Kenwood Arthur, P. O. Box 575, Sitka, Alaska (g) 54

YOUNG, Mr. Gordon A., Mene Grande Oil Co., Apartado 709, Caracas, Venezuela (eh) 51

YOUNG, Dr. Keith, Dept. of Geology, University of Texas, Austin, Texas (ah) 47

YOUNG, Mr. Richard A., 350 W. 4th, N., Richfield, Utah (g) 52

YOUNGDAHL, Miss Olga E., 734 - 17th St., Boulder, Colo. (d) 50

YOUNGQUIST, Mr. C. V., Dept. of Natural Resources, Div. of Water, 1562 W. 1st Ave., Columbus 12, Ohio (g) 36

YU, Dr. King, 22 Hillyer St., Orange, N. J. (g) 49

ZABRISKIE, Mr. Walter E., Three States Natural Gas Co., Scofield, Utah (bg) 53

ZARUDZKI, Mr. E. F. K., United Geophysical Corp., 531 - 8th Ave., W., Calgary, Alta., Canada (bh) 52

ZELLER, Mr. Robert A., Jr., Hachita, N. Mex. (ah) 53

ZENTNER, Mr. Kurt J., Jr., 2902 Lark Court, Rolling Meadows, Ill. (g) 50

ZETLER, Mr. Bernard David, 1305 Floral St., N.W., Washington, D. C. (e) 47

ZIELBAUER, Mr. Edward J., 7905 Tenth Ave., Inglewood, Calif. (g) 47

ZIES, Dr. Emanuel G., 3803 Blackthorn St., Chevy Chase 15, Md. (ef) 29 (Life Member)

ZIMMERMAN, Mr. Aaron L., U. S. Weather Bureau, 9th and I, Sacramento, Calif. (cg) 55

ZIMMERMAN, Mr. Charles C., Keystone Exploration Co., 2813 Westheimer, Houston, Texas (abdh) 38

ZIMMERMAN, Mr. John, Jr., Bakersfield College, 1801 Panorama Dr., Bakersfield, Calif. (bf) 53

ZIRBEL, Mr. N. N., 1922 W. Gray, Houston 19, Texas (bdh) 53

ZMUDA, Dr. Alfred J., 6109 - 41st Ave., Hyattsville, Md. (d) 55

ZOCH, Mr. Richmond T., 6520 - 40th Ave., University Park, Hyattsville, Md. (cg) 43

ZOLLER, Mr. J. Harold, 1933 Custer, Laramie, Wyo. (g) 52

ZUMBERGE, Dr. James H., Geology Dept., University of Michigan, Ann Arbor, Mich. (eg) 53

ZUNINO, Sr. Juan J., Humberto Primo 3486, Buenos Aires, Argentina (abdh) 50

ZWICKY, Prof. Fritz, California Institute of Technology, Pasadena 4, Calif. (dgh) 45

CORPORATION MEMBERS

California Research Corp., 200 Bush St., San Francisco 4, Calif. (Dr. N. Allen Riley, representative)

Carter Oil Co., P. O. Box 801, Tulsa, Okla. (Mr. R. N. Meinert, representative)

Exploration and Production Research Division, Shell Development Co., 3737 Bellaire Blvd., Houston 25, Texas (Dr. C. H. Fay, representative)

Geophysical Research Corp., 136 Mohawk Blvd., Tulsa 6, Okla. (Mr. John E. Owen, representative)

Geotechnical Corp., 3712 Haggar Dr., P. O. Box 7166, Dallas 9, Texas (Dr. Roland F. Beers, representative)

Gulf Research and Development Co., Gulf Oil Corp., P. O. Drawer 2038, Pittsburgh 30, Pa. (Dr. Leo J. Peters, representative)

Houston Technical Laboratories, 2424 Branard St., P. O. Box 6027, Houston 6, Texas (Mr. N. C. Harding, representative)

Leggette, Brashears, and Graham, 551 Fifth Ave., New York 17, N. Y. (Dr. Jack B. Graham, representative)

Magnolia Petroleum Co., P. O. Box 900, Dallas 1, Texas (Mr. Henry C. Cortes, representative)

Chas. T. Main, Inc., 80 Federal St., Boston, Mass. (Mr. Byron O. McCoy, representative)

Meyer and Achtschin, 1400 Republic National Bank Bldg., Dallas 1, Texas (Mr. W. C. Bednar, representative)

Mount Sopris Instrument Corp., 1320 Pearl St., Boulder, Colo. (Mr. Fred E. Fowler, representative)

Ohio Oil Co., Research Dept. Library, P. O. Box 269, Littleton, Colo. (Mr. P. M. Konkel, representative)

Pan American Petroleum Corp., P. O. Box 591, Tulsa, Okla. (Dr. Daniel Silverman, representative)

Parsons, Brinckerhoff, Hall, and Macdonald, 51 Broadway, New York 6, N. Y. (Mr. G. Gale Dixon, representative)

Ralph M. Parsons Co., 617 S. Olive St., Los Angeles 14, Calif. (Mr. James E. Halferty, representative)

Ranney Method Water Supplies, 841 Alton Ave., Columbus 3, Ohio (Mr. Fred H. Klaer, Jr., representative)

Ruska Instrument Corp., 4607 Montrose Blvd., Houston 6, Texas (Mr. S. H. Buckley, representative)

Seismograph Service Corp., P. O. Box 1590, Kennedy Bldg., Tulsa 1, Okla. (Mr. G. H. Westby, representative)

Shell Oil Co., 50 W. 50th St., New York 22, N. Y. (Mr. F. Goldstone, representative)

Texas Instruments Inc., 6000 Lemmon Ave., Dallas 9, Texas (Dr. J. A. F. Gerrard, representative)

United Gas Corp., P. O. Box 1407, Shreveport, La. (Mr. H. I. Meyer, representative)

Vector Manufacturing Co., P. O. Box 18212, Houston 23, Texas (Mr. J. E. Buescher, representative)

Geographical List of Members

February 10, 1957

Alabama

Birmingham--C. R. Jobe (c), P. L. Sharkey (cg), T. A. Simpson (g), N. F. Williams (g)
Huntsville--D. W. Gates (abdefgh), F. I. Ordway, III (acd), G. H. R. Reisig (ac)
Maxwell Air Force Base--C. P. Cloughly (c)
Mobile--W. A. Riggs (abfgh)
Montgomery--J. W. Kodis (abcd), G. A. Llano (g), A. R. Long (cg), F. K. Morris (efgh), F. C. Pate (ceg), W. H. Robinson (g)
Springhill--F. F. Escoffier (eg), G. W. Swindel, Jr. (g)
University--W. B. Jones (d), D. B. Knowles (g), P. E. LaMoreaux (g), W. J. Powell (g)

Alaska

Anchorage--M. E. Nason (d), L. W. Tourville (c), R. M. Waller (g)
College--C. T. Elvey (cd), V. P. Hessler (d), C. J. Juedes (c), F. H. Leinbach, Jr. (d), W. B. Murcray (cdfh), L. Owren (d), T. L. Pewe (cg), M. Sugiura (d), W. S. Wilson (cd)
Fairbanks--M. C. Brewer (bd), T. C. Mathews (bcgh)
Juneau--R. I. Mayo (g)
Palmer--C. W. Wilson (g)
Sitka--J. L. Bottum (bd), K. A. Youmans (g)
Spenard--G. E. Fowler (abcfgh)

Arizona

Bisbee--J. F. Appleby (cg), J. A. Copeland (c), G. E. Daniels (cg), C. E. Erickson (cg)
Douglas--G. R. Fowles (d)
Flagstaff--C. G. Evensen (abcdefgh)
Fort Huachuca--M. O. F. Schroeder (ce)
Globe--E. Antevs (cg)
Grand Canyon--M. E. Kofford (fgh)
Jerome--R. W. Baldwin (bdeg), A. A. Brant (bcdgh)
Phoenix--L. R. Jurwitz (c), P. M. Lewis (ag), H. E. Skibitzke (ag), S. F. Turner (g)
Prescott--A. A. Still (abdfh)
San Manuel--E. J. McCullough, Jr. (bdh)
Scottsdale--W. L. Groene (c), H. J. Thiele (g)
Tempe--J. S. Horton (g), L. R. Rich (g)
Tucson--R. A. Bryson (c), M. E. Cooley (fg), G. E. Davis (g), R. B. DesJardins (c), L. W. Douglas (bc), J. E. Fletcher (g), L. Gwaltney (c), L. C. Halpenny (g), L. A. Heindl (fg), B. Hubbard (abdeh), P. W. Johnson (fg), A. R. Kassander, Jr. (bg), W. C. Lacy (bdfh), E. B. Mayo (fh), J. E. McDonald (c), A. M. Rugg, Jr. (dh), E. Schulman (cg), H. C. Schwalen (cg), G. E. P. Smith (g), R. F. White (bd)
Warren--W. D. Ohmstede (ce)

Arkansas

Benton--B. F. Armbrust, Jr. (f)
El Dorado--L. E. Garrison (e), C. J. Hoke (abg)
Fayetteville--K. Engler (g), P. K. Kuroda (efg)
Fort Smith--J. L. Saunders (g)
Harrisburg--C. V. Freeman (bdfgh)
Hot Springs--D. S. Libbey (cg)
Little Rock Air Force Base--J. G. Gamble (ce), H. C. Getty (cg), E. B. Madden (g), J. H. McHughs (cg), E. C. Meserve (cg), I. E. Miller (g), J. W. Moses (cg), M. S. Petersen (g), J. C. Pyle (g), J. E. Reed (befgh), R. T. Sniegocki (abdgh)
North Little Rock--O. B. Yaeger (g)
Stuttgart--R. G. Kazmann (g)

California

Albany--F. H. Moffitt (aeg)
Alhambra--G. F. Francis (b), H. C. Troxell (gh)
Altadena--S. E. Blewett (c), E. Bollay (ceg), T. H. Braun (b), K. E. Hunter (bdh), R. A. Peterson (g)
Anaheim--W. L. Burnham (g)
Aptos--C. S. Jarvis (egh)
Arcadia--A. L. Himelhoch (g)
Arlington--P. D. Williams (d)
Avenal--W. D. M. Reeves (g)
Bakersfield--W. T. Balch (cg), J. S. Bigelow (h), E. S. Bliss (g), J. G. Cole (bdegh), C. E. Johnson (g), J. C. Manning (g), L. Schiff (g), C. H. Williams (g), J. Zimmerman, Jr. (bf)
Belmont--H. E. Root (cg)
Berkeley--F. Adams (g), J. E. Alverson (cg), H. W. Anderson (cg), F. B. Blanchard (g), G. B. Bodman (g), L. N. Brown (g), P. Byerly (bh), A. S. Campbell (e), C. W. Chesterman (fh), N. Chien (eg), F. B. Clendenen (g), A. Court (cg), P. R. Day (g), H. A. Einstein (g), W. L. Fons (cg), C. M. Gilbert (efg), S. T. Harding (g), N. E. A. Hinds (befg), J. W. Johnson (eg), G. Kalkanis (ceg), P. F. Keim (g), S. R. Keim (egh), J. E. Kesseli (cefg), J. B. Leighly (cg), L. B. Loeb (cd), M. Markowitz (ceg), W. W. McLaughlin (g), C. Meyer (abdf), K. B. Morrissey (cg), E. L. Neff (g), R. D. Ogg (e), J. B. Orr (f), T. H. Pagenhart (g), E. R. Rowe (cg), F. C. Scobey (g), R. E. Storie (g), D. Tocher (abefh), D. K. Todd (ceg), P. D. Trask (ceg), F. T. Turcotte (befh), F. J. Turner (h), J. Verhoogen (bdfh), R. L. Wiegel (e), H. Williams (efh), E. H. Wisser (fh)
Beverly Hills--C. Aston (abd), T. V. Crawford (cg)
Big Sur--G. G. Healey (d)
Bishop--T. J. Henderson (cg)
Burlingame--E. W. Adams (abcdefgh), K. Kaplan (e)
Campbell--A. E. Jones (bfg), J. H. Snyder (g)
Camp Irwin--K. E. Beebe (eg)
Carmel--C. P. Vetter (acg)
Carmichael--F. C. Craig (g), W. W. Peak (g)
China Lake--C. L. D'Ooge (c), P. St. Amand (abdh)
Citrus Heights--J. D. Goodridge (cg)
Claremont--J. F. McAllister (f), W. J. Miller (befh), J. S. Shelton (bcfgh), W. C. Smith (fgh)
Cloverdale--G. Dewart (f)
Coleta--E. F. Serr, III (cg)
Concord--C. A. Morelli, II (abcfgh)
Covina--E. A. Withers (g)
Culver City--W. F. Garber (ceg)
Daly City--W. A. Waldorf (bcg)
Danville--R. W. Goranson (bfh)
Davis--L. J. Booher (g), F. A. Brooks (c), R. H. Burgy (g), L. D. Doneen (g), R. M. Hagan (g), A. H. Hendrickson (g), C. F. Kelly (cg), J. N. Luthin (cg), J. C. Marr (g), V. H. Scott (g), E. F. Serr, II (g), F. J. Veihmeyer (cg)
El Cajon--J. Kahl (ce)
El Centro--J. D. Hess (g)
El Cerrito--C. A. Davidson (ag), E. D. Kane (c)
Encinitas--M. C. Chittenden (b), J. D. Isaacs (ed)
Encino--F. D. Voris (cd)
Eureka--I. E. Anderson (cg), V. J. Hansen (cg), J. J. O'Brien, Jr. (g)
Fresno--A. R. Addington (bg), L. Costedoat (g), C. Hobe (abg), H. Karrer (g), E. F. Sullivan (g), C. L. Walton (g)
Fullerton--K. E. Brunot (e), J. W. Higgins (afgh), J. W. Spencer (bdegh), R. E. Stevenson (e)
Gardena--B. T. Pleimann (bf)
Glendale--M. Bookman (g), S. F. Bush (cg), J. E. Jones

(g), F. E. Schoonover (bg), E. R. Stauffacher (cg), F. E. Tatum (g)
Glendora--C. C. Green (g), E. L. Hamilton (cg), R. A. Merriam (g), P. B. Rowe (cg), J. D. Sinclair (cg)
Goleta--J. B. Powers (c)
Granada Hills--F. S. Johnson (cd)
Hawthorne--E. C. Hartman (cdg)
Hollywood--O. H. Truman (ab)
Huntington Park--M. N. E. Rifai (g)
Imperial Beach--H. C. Myers (g), G. F. Warn (abcdefgh)
Independence--G. A. Lewis (g)
Inglewood--W. O. Byrd (a), W. Silva (b), J. R. Stipp (g), E. J. Zielbauer (g)
Kentfield--J. S. Cotton (cgh)
La Canada--W. J. Carroll, Jr. (cg), J. W. Dunham (e), R. L. Nevin (g)
Lafayette--J. E. Taylor (g)
La Habra--E. C. Nixon (h), N. A. Riley (cgh), G. C. Werth (bde)
La Jolla--R. S. Arthur (ce), M. N. Bramlette (aeg), E. E. Collias (e), C. S. Cox (e), T. Cromwell (e), C. Eckart (de), W. M. Elsasser (cd), T. R. Folsom (e), J. D. Frautschy (aeg), E. D. Goldberg (ae), G. W. Groves (e), D. L. Inman (eg), L. W. Kidd (e), J. A. Knauss (e), L. Lek (e), R. M. Lesser (ce), R. G. Mason (abdefh), G. F. McEwen (ceg), W. H. Munk (beh), P. Osborn (e), P. H. Ottosen (e), F. B. Phleger (e), R. W. Raitt (abceh), N. W. Rakestraw (eg), R. R. Revelle (cefgh), R. W. Rex (abcdefgh), A. F. Richards (ef), M. K. Robinson (e), P. Rudnick (e), M. B. Schaefer (e), F. P. Shepard (befh), G. G. Shor, Jr. (beh), W. G. Van Dorn (e), G. H. Volkmann (e), W. S. Wooster (e)
Lake Hughes--O. R. Rudder (c)
La Mesa--J. B. Smyth (bc)
La Mirada--V. Vanni (eg)
Lodi--F. H. Watson, Jr. (cg)
Lomita--J. C. Alter (cg)
Lompoc--P. R. Nixon (cg)
Long Beach--R. S. Brown (fg), W. A. Kelly (dfgh), W. L. Knight (bdeh), F. Kunkel (g), D. H. McKillop (g), F. F. Mead (abeg), F. S. Riley (g)
Los Altos--D. R. Schink (e), S. H. Williston (d)

Nigeria--J. D. Closs (bef)

Northern Rhodesia--J. Berning (abdfh)

Norway--T. F. W. Barth (f), C. L. S. Godske (c), E. Raestad (g), S. Rosseland (ad), H. U. Sverdrup (cde)

Pakistan--A. M. Khan (bdfgh), S. Mahmud (abcdg), C. M. Umar (g)

Persian Gulf--J. A. Christensen (abd)

Peru--J. A. Broggi y Morel (abcdefgh), A. A. Giesecke, Jr. (bcdh), H. L. Hosmer (dfh), P. G. Ledig (bd), F. C. Nieri (abdfh), S. L. Schoff (ceg)

Philippine Islands--N. Badillo (g), C. E. Deppermann, S.J. (cd), A. O. Hizon (abcg), D. I. Ilio (ag), K. W. B. Iten (h), C. M. Legaspi (abcdefgh), J. P. Mamisao (cg), N. B. Sauve (abdh)

Portugal--J. T. da Fouseca Oliveira (abg), G. H. Hazen (ab), F. E. Wimbish (ag)

Saudi Arabia--S. D. Bowers (abfg), R. A. Bramkamp (begh), R. B. Carr (abd), D. A. Holm (abcefgh), J. A. McInnis (a), W. Q. Wright, Jr. (abcdgh)

Somalia--R. H. Talty (b), G. R. Wilson (g)

South Africa--V. L. Bosazza (efgh), B. B. Brock (bdefh), F. S. Burdecki (ace), J. F. Enslin (ad), P. G. Gane (bd), B. D. Maree (abcdefgh), N. Shand (cg), Y. H. Smitter (aeg), A. M. van Wijk (abcd), J. R. Vegter (bdg), J. C. Webster (d), O. Weiss (abcdefgh)

Southern Rhodesia--P. H. Haviland (acdfg), R. R. Staples (g)

Spain--A. Due, S.J. (abc), R. Gea J. (dgh), A. Lopez Arroyo (ab)

Sweden--M. Båth (b), M. A. Eaton (c), B. M. Hellstrõm (g), I. Hessland (eg), W. A. Mordy (c), C.-G. Rossby (ce), K. J. M. Sundquist (g), G. S. Tornquist (abdfh), P. W. Werner (g)

Switzerland--M. R. de Quervain (g), T. Hugi (fg), L. Mazurczak (fgh), H. J. Tschopp (bdefgh), M. B. Vuagnat (efh), E. Wenk (fh)

Syria--D. J. Burdon (cdefg)

Tasmania--S. W. Carey (h)

Thailand--H. F. Haworth (g), B. Kanchanalak (cg), S. Pachimkul (a), R. L. Pendleton (g)

Trieste--C. Morelli (abcdh), S. Polli (ce)

Tunisia--J. Tixeront (g)

Turkey--H. H. Conturk (g), K. Ergin (abdeh), H. P. Hall (bgh), I. Ketin (bh), E. Lahn (bfgh), H. Pektas (e), N. Pinar (bfh), H. F. Sagoci (abd), T. Sarpkaya (eg)

Venezuela--P. I. Aguerrevere (bdg), S. E. Aguerrevere (abc), J. W. Butler, Jr. (bdfh), P. P. Conrad (abcdegh), R. Convit G. (cg), H. L. Copeland (bh), W. J. Cox, Jr. (ef), D. W. Danz (b), E. M. Davin (bh), L. A. E. Doe (ceg), A. D'Santiago (cg), G. Feo-Codecido (fg), J. J. Gschwendtner (cg), J. I. Irujo (bceg), P. Jacobsen, Jr. (abdh), H. M. Johnson (abdeh), J. F. Judson (b), E. L. Krinitzsky (abcg), M. A. Lanz-Lopez (ag), H. P. Laubscher (bfh), L. J. Medina (g), C. J. Metzger (bdefgh), A. B. Morrill (cg), L. A. Nelson (abdh), J. H. Pantin (abcdefgh), A. E. Pardo (cg), A. J. Richardson (abd), R. H. Robie (abcegh), A. C. Romero (ad), C. G. Schauble (b), R. H. T. Schut (bh), A. Schwarck A. (bgh), R. J. Smith (abh), O. A. Sucre A. (cg), H. W. Thoms (cg), J. C. Van Wynen (bh), H. Vollenweider (acdefg), A. J. Vollmer (g), J. M. Ward (g), N. E. Weisbord (acefg), F. W. Wright, Jr. (cdfh), G. A. Young (eh)

Yugoslavia--R. Turajlic (ad)

Union and Section Committees

[These are in the process of formation. The list will be published subsequently in the Transactions.]

- Executive Committee of the Union

- Standing Committees of the Union
  - International Participation
  - Statutes and By-Laws
  - Membership
  - Meetings
  - Nominations
  - Budget
  - Audit
  - Editorial and Publication

- Special Committees of the Union
  - Geophysical and Geological Study of Continents
  - Cosmic-Terrestrial Relationships
  - Award of the William Bowie Medal
  - Resolutions
  - Award in Terrestrial Magnetism and Electricity
  - Tellers
  - Advertising
  - Relations of American Geophysical Union with American Geological Institute
  - Relationship of American Geophysical Union to International Geophysical Year

- Regional Committees
  - North Central Regional Committee
  - Pacific Northwest Regional Committee
  - Pacific Southwest Regional Committee
  - Mid-Pacific Regional Committee

- Representatives
  - American Association for the Advancement of Science, Representatives on the Council
  - American Geological Institute, Board of Directors
    - Government Relations Committee
  - National Research Council, Division of Earth Sciences
  - National Research Council, Division of Physical Sciences
  - U. S. National Committee for the International Geophysical Year

- Committees of the Sections
  - Geodesy
    - Executive Committee
    - Resolutions
    - Program
    - Nominations
  - Seismology
    - Executive Committee
    - Resolutions
    - Nominations
  - Meteorology
    - Executive Committee
    - Upper Atmosphere
    - Atmospheric Diffusion
    - Atmospheric Chemistry
    - Cloud Physics ?
    - Chemical Meteorology
    - Interactions of the Atmosphere with the Sea (joint committee with the Section of Oceanography and the American Meteorological Society)
    - Nominations
    - Program
  - Terrestrial Magnetism and Electricity
    - Executive Committee
    - Nominations
    - Resolutions
  - Oceanography
    - Executive Committee
    - Nominations
    - Interactions of the Atmosphere with the Sea (see above under Meteorology)
  - Volcanology, Geochemistry, and Petrology
    - Executive Committee
    - Nominations
  - Hydrology
    - Executive Committee
    - Program
    - Awards
    - Nominations
    - Permanent Research Committees
      - Precipitation
      - Erosion and Sedimentation
      - Evaporation and Transpiration
      - Surface Water
      - Snow, Ice, and Glaciers
      - Ground Water
  - Tectonophysics
    - Executive Committee
    - Nominations

List of Publications

[Arrangements are being entered into with a reprint company to have back numbers reprinted, most of which are now out of print. Watch Special Announcements in the Transactions for further details. The Transactions from 1954 to the present are all still available, but as of July 1, 1957, it is anticipated that the Transactions for 1954 will be turned over to the reprint concern. Watch Special Announcements in the Transactions also for further information regarding this matter.]

Volume No.	Year	Title	No. pages	Price postpaid, volume
1	1920	Transactions (Reprint and Circular Series, National Research Council No. 11)	57	
2	1921	Transactions (Bull. National Research Council, No. 17)	108	
3	1922	Not published	..	
4	1923	Transactions (Bull. NRC, No. 41)	150	
5	1924	Not published	..	
6	1925	Transactions (Bull. NRC, No. 53)	80	
7	1926	Transactions (Bull. NRC, No. 56)	134	
8	1927	Transactions (Bull. NRC, No. 61)	297	
9	1928	Transactions (Bull. NRC, No. 68)	103	
10-11	1929-30	Transactions (all Sections)	314	
12	1931	Transactions (all Sections)	229	
13	1932	Transactions (all Sections)	401	
14	1933	Transactions (all Sections)	521	
15	1934	Transactions Part I (all Sections except Hydrology)	258	(See note near top of this page)
	1934	Transactions Part II (Hydrology)	376	
16	1935	Transactions Part I (all Sections except Hydrology)	364	
	1935	Transactions Part II (Hydrology)	166	
17	1936	Transactions Part I (all Sections except Hydrology)	260	
	1936	Transactions Part II (Hydrology and Regional Meetings, Hydrology)	304	
18	1937	Transactions Part I (all Sections except Hydrology)	264	
	1937	Transactions Part II (Hydrology and Regional Meetings, Hydrology)	300	
19	1938	Transactions Part I (all Sections)	585	
	1938	Transactions Part II (Regional Meetings, Hydrology)	159	
20	1939	Transactions Part I (Regional Meetings, Hydrology)	140	
	1939	Transactions Part II (Symposium on floods)	94	
	1939	Transactions Part III (all Sections except Hydrology)	250	
	1939	Transactions Part IV (Hydrology)	257	
21	1940	Transactions Part I (Stanford University, Regional Meetings, Hydrology)	144	
	1940	Transactions Part II (Washington Annual Meetings, all Sections)	632	
	1940	Transactions Part III (Richmond Symposium and Seattle Regional Meetings, Hydrology)	285	
	1940	Transactions Part IV (Columbus symposia: Applications of mathematics in the Earth sciences and Hydrologic problems in the Ohio and Michigan basins)	86	
22	1941	Transactions Part I (Sacramento Regional Meeting, Hydrology)	216	
	1941	Transactions Part II (Washington Annual Meetings, all Sections except Hydrology)	368	
	1941	Transactions Part III (Washington Annual Meeting, Hydrology)	452	
23	1942	Transactions Part I (Dallas and Pasadena Regional Meetings, Hydrology)	172	
	1942	Transactions Part II (Washington Annual Meetings, all Sections)	570	

Volume No.	Year	Title	pages	Price postpaid, volume
24	1943	Transactions Part I (Washington Annual Meetings, all Sections except Hydrology)	332	(See note near top of page 89)
	1943	Transactions Part II (Washington Annual Meeting, Hydrology)	454	
	1943	Transactions Part III (Corvallis Regional Meeting, Hydrology, and Western Snow Conference) and Addendum.	105	
25	1944	Transactions Part I (Berkeley Regional Meeting, Hydrology, and Western Snow Conference)	187	
	1944	Transactions Part II (Washington Annual Meeting, General Assembly, Geodesy, Seismology, Minutes of all Meetings)	203	
	1944	Transactions Part III (Washington Annual Meeting, Meteorology)	138	
	1944	Transactions Part IV (Washington Annual Meeting, Terrestrial Magnetism and Electricity, Oceanography, Volcanology, and Tectonophysics)	142	
	1944	Transactions Part V (Washington Annual Meeting, Hydrology: Reports)	160	
	1944	Transactions Part VI (Washington Annual Meeting, Hydrology: Papers)	236	
26	1945	Three bimonthly numbers starting with August	482	
27	1946	Six bimonthly numbers	926	
28	1947	Six bimonthly numbers	980	
29	1948	Six bimonthly numbers	956	
30	1949	Six bimonthly numbers	950	
31	1950	Six bimonthly numbers	968	
32	1951	Six bimonthly numbers	964	
33	1952	Six bimonthly numbers	956	
34	1953	Six bimonthly numbers	986	
35	1954	Six bimonthly numbers, $2.00 each	1026	$ 9.00
36	1955	Six bimonthly numbers, $2.00 each	1132	9.00
37	1956	Six bimonthly numbers, $2.00 each	812	10.00
38	1957	Six bimonthly numbers, $2.00 each; subscription for calendar year, $10.00.		
Monograph Series				
1	1956	Antarctica in the International Geophysical Year (with 42 × 42 inch map of the Antarctic).	134	6.00
Special Publications				
	1920-44	Index (combined author and subject), volumes 1-25.	144	4.00

		Years 1951-1954 available through Government Printing Office, Washington, D. C., at a price of $1.25	208	
		List of Members and Officers:		
	1948	July 10, 1948 (Part 2 of August 1948).	79	1.00
	1950	September 10, 1950 (Part 2 of October 1950)	116	1.50
	1952	September 10, 1952 (Part 2 of October 1952)	120	1.50
	1954	November 10, 1954 (Part 2 of December 1954)	132	2.00
	1957	February 10, 1957 (included in April 1957).	90	1.00

Orders, with checks payable to the American Geophysical Union, should be addressed to

American Geophysical Union
1515 Massachusetts Ave., N.W.
Washington 5, D.C., U.S.A.

American Geophysical Union

PROPOSAL FOR MEMBERSHIP

To: Chairman, Committee on Membership, American Geophysical Union,
1515 Massachusetts Ave., Northwest, Washington 5, D. C.

Date____________________

1. Application is hereby made for membership / associate membership / student membership in the Union by

Name (in full)____________________

2. Title under which it is desired to be known (as Mr., Dr., Prof., Sr.)__________

3. Address____________________ Zone No._____

4. Place of birth____________________ Date_____

5. Citizen of____________________

6. Present position, title____________________ Since_____

7. Former positions and experience in geophysics or allied fields with approximate periods*

Dates	

8. Education: Universities or Colleges attended and degrees received*

Dates	

9. Section or sections with which affiliation is desired (see back)__________

10. QUALIFICATIONS—Give sufficient information to show that nominee meets the requirements given on the back of this form*

____

____

____

11. Signature of applicant____________________

12. Signatures of at least two sponsors who are members__________

____________________ ____________________

* If more space is needed, use the reverse side or added sheets showing item number.

SECTIONS OF UNION

(a) Geodesy, (b) Seismology, (c) Meteorology, (d) Terrestrial Magnetism and Electricity, (e) Oceanography, (f) Volcanology, (g) Hydrology, (h) Tectonophysics.

QUALIFICATION OF MEMBERS

(To be eligible for grade of Member, nominee must qualify under A or B.)

A. Active contribution to geophysical research through observation, publication, teaching, or administration.

Definite evidence should be presented to Membership Committee. "Publication" may include books, articles, unpublished manuscripts, inventions, or development of geophysical instruments.

B. Active practical application of geophysical research.

It should be shown that the nominee's work has not been purely routine, but that it has tended to create new knowledge of, or to broaden or strengthen the application of, geophysical research.

In general the minimum qualifications for membership will be not less than three years of professional experience in some phase of geophysics.

QUALIFICATION OF ASSOCIATE MEMBERS

Active interest in physical processes of the Earth or technical assistance in the application of geophysics.

In general the minimum qualification for associate membership will be a college degree in some field of geophysics or allied science or a comparable period of training and experience.

VOLUME 39 **FEBRUARY 1958** **NUMBER 1**

CONTENTS

PAPERS

General

Reconnaissance Study of Erosion and Deposition Produced by the Flood of August 1955 in Connecticut M. Gordon Wolman and Jack P. Eiler 1
Correlation of Rainfall Intensity and Topography in Northern California .... Ray K. Linsley 15
Some Results of Geothermal Investigations of Permafrost in Northern Alaska .... Max C. Brewer 19

Geodesy

A Method for the Measurement of Absolute Gravity Richard A. Haubrich, John C. Rose, and G. P. Woollard 27

Terrestrial Magnetism and Electricity

Least Squares in Magnetic and Gravity Interpretation .... Donald H. Hall 35

Meteorology

Synoptic and Climatological Problems Associated with the General Circulation of the Arctic Jerome Namias 40
The Accuracy of Wind-Speed Estimates at Sea .... Charles F. Brooks and Eleanor S. Brooks 52
Effective Coefficients of Diffusivity for Atomic Bomb Clouds at One Thousand to Two Thousand Miles Eugene M. Wilkins 58
Precipitation Scavenging from Atomic Bomb Clouds at Distances of One Thousand to Two Thousand Miles Eugene M. Wilkins 60
A Max-Min Dew-Point Hygrometer .... C. B. Tanner and V. E. Suomi 63

Hydrology

Longitudinal and Transverse Diffusion in Granular Deposits .... G. de Josselin de Jong 67
Application of Statistical Methods to the Analysis of Ground-Water Levels Irwin Remson and J. R. Randolph 75
Use of Infiltration Equation Parameters to Evaluate Infiltration Differences in the Field D. Swartzendruber and M. R. Huberty 84
Problems Encountered in the Utilization of Ground-Water Reservoirs .... Raphael G. Kazmann 94
Upper and Lower Frequency Curves for Peak Rates of Runoff .... W. D. Potter 100

Seismology

A Long-Period Seismograph System .... Frank Press, Maurice Ewing, and Francis Lehner 106

TECHNICAL NOTES

Oceanography

Shore-Based Recorder of Low-Frequency Ocean Waves .... Frank E. Snodgrass 109
Offshore Recording of Low-Frequency Ocean Waves .... F. Snodgrass, W. Munk, and M. J. Tucker 114

Hydrology

A Fluid Level Sensing Device of Simple Design .... Reinhold Gerharz 121

DISCUSSIONS

Hydrology

Permeability and Infiltration Relationships in One Dimensional Infiltration in a Uniform Soil: J. R. Philip 123
A Correlation of the Characteristics of Great Storms: Ven Te Chow, D. A. Kraijenhoff van de Leur, and M. C. Boyer 124
The Transport of Sand by Wind: R. A. Bagnold and Edwin F. Ford 127
Rainfall-Runoff Relations for Small Basins: Louis A. Koffman, and J. F. Miller and J. L. H. Paulhus 128

Tectonophysics

A Hypothesis of Formation of Mountains and Continents: Robert R. Wheeler, William A. Wiebenga, and B. D. Aggarwala and Edward A. Saibel 129

CONTENTS

PAPERS

GEODESY

The Establishment of a Calibration Standard for Gravimeters in Eastern Canada and the United States
M. J. S. Innes 195

GEOMAGNETISM AND AERONOMY

Tropospheric Bending of Radio Waves.......L. J. Anderson 208
Seasonal Changes in Day-to-day Variability of Upper Air Winds Near the 100-km Level of the Atmosphere
E. H. Vestine 213

OCEANOGRAPHY

Water Gravity Waves Generated by a Moving Low Pressure Area
R. L. Wiegel, C. M. Snyder, and J. E. Williams 224
A New Method for Measuring the Thermal Microstructure of the Sea
R. J. Urick, L. C. Pharo, and E. Skudrzyk 237

METEOROLOGY

The Distribution of Ammonia and Nitrate in Rain Water over the United States.....Christian E. Junge 241

HYDROLOGY

Experimental Studies on the Relation between Transpiration Rate and Meteorological Elements
Yoshito Yamaoka 249
The Total Transpiration from a Forest.......Yoshito Yamaoka 266
A Method for Determining the Average Precipitation between Curved Isohyets......Guy A. Franceschini 273
The Thermal Regime of an Arctic Lake.......Max C. Brewer 278
Rainfall Energy and Its Relationship to Soil Loss...........Walter H. Wischmeier and Dwight D. Smith 285
Some Methods of Alleviating Surface Clogging in Water Spreading with Emphasis on Filters
Leonard Schiff and Curtis E. Johnson 292
Evapotranspiration Estimates from Heat-Budget Measurements over a Field Crop
V. E. Suomi and C. B. Tanner 298

TECTONOPHYSICS

Strength Studies of High-Density Snows.......Theodore R. Butkovich 305

SEISMOLOGY

Studies on Wave Propagation in Granular Media.......Paul Lieber and Arthur Farmer 313

VOLCANOLOGY, GEOCHEMISTRY, AND PETROLOGY

Absolute Age of Early Precambrian Rocks in the Bighorn Basin of Wyoming and Montana, and Southeastern Manitoba.......P. W. Gast, J. L. Kulp, and L. E. Long 322

DISCUSSIONS

OCEANOGRAPHY

Evidence for a Critical Wind Velocity for Air-Sea Boundary Processes, and Change in the Relationship Between Wind and Surface Water Movement at Higher Wind Speeds: Hugo Mandelbaum.......... 335

HYDROLOGY

A Criterion for Selection of Length of Record for a Moving Arithmetic Mean for Hydrologic Data: T. E. A. van Hylckama and Robert T. Beaumont....... 337

REVIEWS, ABSTRACTS, AND BIBLIOGRAPHY

REVIEWS AND ABSTRACTS

Felix Chayes, Petrographic Modal Analysis—An Elementary Statistical Appraisal, George T. Faust...... 339

VOLUME 39 JUNE 1958 NUMBER 3

CONTENTS

TWENTIETH AWARD OF THE WILLIAM BOWIE MEDAL

Citation .... Walter H. Bucher 385
Presentation .... Lloyd V. Berkner 387
Response and Acceptance, and Address: In the Borderland between Geophysics and Engineering J. Th. Thijsse 387

PAPERS

GEODESY

Tests of a New Submarine Gravity Meter .... F. N. Spiess and G. L. Brown 391

METEOROLOGY

The Use of Evenly Spaced Hemispheres to Evaluate Aerodynamic Forces on a Soil Surface .... W. S. Chepil 397

OCEANOGRAPHY

Probability Distributions of Water-Wave Slopes under Conditions of Short Fetch .... Allen H. Schooley 405
Comparative Ice Conditions in North American Arctic, 1953 to 1955, Inclusive John J. Schule, Jr., and Walter I. Wittmann 409

HYDROLOGY

Symposium on Radioactivity in Natural Waters

- Time of Flow Studies, Ottawa River, Lima, Ohio Conrad P. Straub, F. J. Ludzack, G. R. Hagee, and A. S. Goldin 420
- Radiotracer Experiments in the Mohawk River, New York, to Study Sewage Path and Dilution E. S. Simpson, W. A. Beetem, and F. H. Ruggles 427
- Radioactive Tracers in Hydrologic Studies .... Frank L. Parker 434
- The Travel Time of Radioactive Wastes in Natural Waters .... G. T. Bryant and J. C. Geyer 440
- Tracing Moisture Movement in Slick-Spot Soils with Radiosulfur: Part I J. V. Jordan, G. C. Lewis, and M. A. Fosberg 446
- The Distribution of Radioactivity from Rain .... Lloyd R. Setter and Conrad P. Straub 451
- Uranium and Radium in the Ground Water of the Llano Estacado, Texas and New Mexico F. B. Barker and R. C. Scott 459
- Disposal of Radioactive Waste on Land .... H. H. Hess and W. R. Thurston 467

Fitting a Generalized Log-Normal Distribution to Hydrologic Data .... D. L. Brakensiek 469

SEISMOLOGY

Seismological Studies of the Western Rift Valley of Africa .... George H. Sutton and Eduard Berg 474
Short-Period Oceanic Surface Waves of the Rayleigh and First Shear Modes . . Jack Oliver and Maurice Ewing 482
Velocity of Seismic Waves in the Earth's Mantle .... B. Gutenberg 486

LETTERS TO THE EDITOR

Extrapolation of Scalar Magnetic Intensity Along a Radius from the Center of the Earth .... A. Zmuda 490
Parliament of Science, March 15–17, 1958 .... H. G. Wilm 491

REPORT

Report of the Special Committee on the Geophysical and Geological Study of Continents, 1955–1957 G. P. Woollard, Chairman 492

DISCUSSION

HYDROLOGY

The Effect of Non-Representative Sampling on Linear Regressions as Applied to Runoff: N. J. Cochrane, J. L. McGuinness and D. L. Brakensiek, Manuel A. Benson, and W. D. Potter 497

UNION, SECTION, AND COMMITTEE ACTIVITIES

THIRTY-NINTH ANNUAL MEETING (1958)

Smoker 556
Symposium on Satellite Geophysical Studies 556
Evening Session 556
Minutes, General Assembly .... A. Nelson Sayre and Waldo E. Smith 557
    Summary Report of the General Secretary .... A. Nelson Sayre 557
    Report of the President .... Presented by Vice President Lloyd V. Berkner 557
    Reports of Standing Committees 558
    Reports of the Committee on Resolutions 558
Minutes of the Sections
    Appendix A—Geodesy .... Frank L. Culley, Secretary 559
    Appendix B—Seismology .... James A. Peoples, Jr., Secretary 559
    Appendix C—Meteorology .... Woodrow C. Jacobs, Secretary 560
    Appendix D—Geomagnetism and Aeronomy .... R. E. Gebhardt, Secretary 562
    Appendix E—Oceanography .... Donald W. Pritchard, Secretary 562
    Appendix F—Volcanology, Geochemistry, and Petrology .... L. Thomas Aldrich, Secretary 563
    Appendix G—Hydrology .... Ralph N. Wilson, Secretary 564
    Appendix H—Tectonophysics .... B. F. Howell, Jr., Secretary 566
Pacific Southwest Regional Meeting Held in Pasadena, February 6–7, 1958 566
Additions to the Membership, February 10, 1957 to April 10, 1958 566

SPECIAL ANNOUNCEMENTS

Back *Transactions* 574
Symposium on Snow and Glaciers 574
Pacific Northwest Regional Meeting to be Held in Portland, Oregon, November 13–14, 1958 574
Pacific Southwest Regional Meeting 574
Fortieth Annual Meeting 574
Twelfth General Assembly, IUGG 574

CONTENTS

PAPERS

GEODESY

Gravity Measurements in the Queen Elizabeth Islands of Arctic Canada .... A. M. Bancroft 615

METEOROLOGY

Planetary Waves and Jet Streams in the Atmosphere .... S.-K. Kao 620

Microvariations of Water Vapor in the Lower Troposphere with Applications to Long-Range Radio Communications .... John R. Bauer and James H. Meyer 624

OCEANOGRAPHY

A Theoretical Analysis of Sea-Ice Strength .... Don L. Anderson and Wilford F. Weeks 632

An Experimental Study of Strength of Young Sea Ice .... Wilford F. Weeks and Don L. Anderson 641

HYDROLOGY

The Effects of Entrapped Gases on the Hydraulic Characteristics of Porous Media Gerald T. Orlob and G. N. Radhakrishna 648

Ground-Water Studies in New Mexico Using Tritium as a Tracer .... Haro von Buttlar and Immo Wendt 660

Factors Affecting Sediment Delivery Rates in the Red Hills Physiographic Area .... Sam B. Maner 669

Effect of Temperature Distribution on Moisture Flow in Porous Materials W. Woodside and J. M. Kuzmak 676

Snow-Melt Degree-Day Ratios Determined from Snow-Lab Data .. Leonard L. Weiss and Walter T. Wilson 681

Two-Dimensional Gravity Drainage Profiles .... B. J. Hollingsworth and H. I. Meyer 689

Rate and Depth of Thaw in Arctic Soils .. J. V. Drew, J. C. F. Tedrow, R. E. Shanks, and J. J. Koranda 697

On the Theoretical Derivation of Darcy and Forchheimer Formulas .... S. Irmay 702

The Measurement of Thermal Conductivity and Diffusivity with Cylindrical Probes J. C. Jaeger 708

SEISMOLOGY

Velocity of Compressional Waves in Some Indian Rocks .... S. Balakrishna 711

VOLCANOLOGY, GEOCHEMISTRY, AND PETROLOGY

K-A and Rb-Sr Methods and Age of Precambrian of USSR .... A. A. Polkanov and E. K. Gerling 713

TECHNICAL NOTE

OCEANOGRAPHY

An Optical Method for the Measurement of Surface Waves in the Laboratory .... Alan J. Faller 716

REPORT

Progress Report, Seismological Laboratory of the California Institute of Technology, 1957 Hugo Benioff, Beno Gutenberg, Frank Press, and C. F. Richter 721

DISCUSSIONS

GEODESY

The Columbus Geoid: William M. Kaula and W. A. Heiskanen 726

Some Comments on the Results Obtained with the Cambridge Pendulum Apparatus in North America: J. C. Dooley and R. L. G. Gilbert 729

HYDROLOGY

A Probe for Measurement of Thermal Conductivity of Frozen Soils in Place: William Woodside and Arthur H. Lachenbruch 730

The Statistical Treatment of Flood Flows: E. J. Gumbel, G. N. Alexander, and P. A. P. Moran 732

Water and Drainage in Semi-Arid Countries: Raphael G. Kazmann and Alfred Loehnberg 736

Some Problems in Non-Artesian Ground-Water Flow: M. Maasland and P. Wilh. Werner 738

REVIEWS, ABSTRACTS, AND BIBLIOGRAPHY

CONTENTS

PAPERS

GENERAL

The Geochemistry of Tritium .... Bruno J. Giletti, Fernando Bazan, and J. Laurence Kulp 807

GEODESY

Distortion in Continental Triangulation .... Charles A. Whitten 819
Geodetic Control in Jungle Areas .... Carl I. Aslakson 821

GEOMAGNETISM AND AERONOMY

Airborne Measurements of Atmospheric Electricity .... J. H. Kraakevik and John F. Clark 827

METEOROLOGY

The 27-day Period in United States Temperatures .... S. W. Visser 835
An Analysis of Some Over-Water Wind Profile Measurements .... N. K. Wagner 845
A Portable Raindrop Recorder for Semi-Continuous Determination of Size Distributions
A. T. Spencer and D. C. Blanchard 853
An Empirical Method for Estimating Wind Profiles over Open, Level Ground
David N. Keast and Francis M. Wiener 858

OCEANOGRAPHY

Characteristics of Waves Generated by a Local Disturbance .... J. E. Prins 865
An Interpretation of the Transverse Component of the Geomagnetic Electrokinetograph
Readings in the Florida Straits off Miami .... Frank Chew 875
Computation of the Ocean-Wave Forces on Inclined Cylinders .... L. E. Borgman 885
The Equilibrium Beach .... William F. Tanner 889

HYDROLOGY

Seepage of Steady Rainfall through Soil into Drains .... Don Kirkham 892
Simultaneous Transfer of Heat and Moisture in Porous Media .... D. A. de Vries 909
Calculation of Total and Component Potentials of Water in Soil .... G. H. Bolt and R. D. Miller 917
Typical Solutions of the Differential Equations of Statistical Theories of
Flow through Porous Media .... A. E. Scheidegger 929
Calibration of Five Small Forested Watersheds .... K. G. Reinhart 933
A Note on the Dispersion of a Salt-Water Boundary Moving through Saturated Sand ..... Erik Eriksson 937
A Note on the Differential Equation of Steady, Gradually Non-Uniform
Flow in Open Channels .... Hsin Kuan Liu 939

SEISMOLOGY

Preliminary Report on the Alaskan Earthquake of April 7, 1958 .... T. Neil Davis 941

VOLCANOLOGY, GEOCHEMISTRY, AND PETROLOGY

Compressibility and Temperature on the Earth's Interior .... Frederico Machado 943
The Nature of the Mohorovicic Discontinuity .... J. F. Lovering 947
A^{40}/K^{40} Age of Gneiss from McMurdo Sound, Antarctica . . S. S. Goldich, A. O. Nier, and A. L. Washburn 956

TECTONOPHYSICS

Density of Basic Rocks at Very High Pressures .... Darrell S. Hughes and Robert G. McQueen 959

DISCUSSIONS

METEOROLOGY

Sky Temperatures in the Imperial Valley of California: Alice M. Stoll, F. A. Brooks and John R. Goss, and C. F. Kelly 966
The Accuracy of Wind-Speed Estimates at Sea: G. Verploegh and Eleanor S. Brooks 968

HYDROLOGY

Correlation of Rainfall Intensity and Topography in Northern California: W. T. Wilson and D. M. Hershfield 970
Relation of Potential Evapotranspiration to Environment and Kind of Plant: M. A. Kohler, Edgar E. Foster, W. O. Drinkwater and B. E. Janes 972
Flood Frequency by Regional Synthesis: Manuel A. Benson, Ray K. Linsley, David M. Hershfield, and R. Robinson Rowe, Gordon L. Long, and Thomas C. Royce 974

INDEX OF SUBJECTS

AAAS, meeting, 766, 933
Abstracting, geophysical, report of committee, 1197
Abstracts
  papers presented at Pacific southwest regional meeting, 538
  papers presented at Thirty-ninth annual meeting, 503
Aerodynamic forces on a soil surface, 397
Aerodynamics, high-speed, 742
Africa, seismological studies, 474
Age of the Baltimore gneiss, 534
Age determination, ionium method, 535
Age of early Precambrian rocks, 322
Age of gneiss, A^{40}/K^{40}, from McMurdo Sound, Antarctica, 956
Age of Precambrian, methods in USSR, 713
Airborne measurements of atmospheric electricity, 827
Airborne particles, contribution to pelagic sediments, 540
Air-sea boundary processes, evidence for a critical velocity, 335
Alaska, geothermal investigations of permafrost, 19
Alaskan earthquake of April 7, 1958, 941
Alpine snowfields, hydrologic features under summer conditions, 524
Amendments, suggested, in Statutes and By-Laws to implement Peoples' report, 764
Ammonia and nitrate, distribution in rain water, 241
Andes, seismic expedition, 1957, 533
Andes, seismic studies, 580
'Angel' echoes, 504
Antarctic notes, IGY, 1223
Antarctic oversnow traverses, 369
Antarctic stations, US-IGY, weather during 1957, 997
Antarctica
  A^{40}/K^{40} age of gneiss from McMurdo Sound, 956
  deep core drilling program, Byrd station, 1021
  quaternary glaciation, McMurdo Sound region, 787
  Ross ice shelf deformation project, 794
  thickness of ice, 772
Aquifer, balance of fresh water and salt water, 512
Aquifers, salt-water encroachment, 541
Arctic
  Canada, gravity measurements, 615
  ice conditions, 409
  ionosphere, ion composition, 520
  lake, thermal regime, 278
  sea-ice studies, 601
  slope sediments, 542
  soils, rate of thaw, 697
  synoptic and climatological problems of circulation, 40
Arithmetic mean for hydrologic data, criterion for length of record, 337
ARRL-IGY propagation research project, 995
Artificial stimulation of rain, 1172
Atlantic
  circulation rates of near-surface waters and the cosmic-ray production of tritium, 516
  expeditions of *Meteor*, 1171
  IGY island observatories, 525
  wave heights and periods, 1064
Atmosphere
  exploring the first mile, 502
  planetary waves and jet streams, 620
  sulfur budget, 520
Atmospheric
  circulation, strength over the north Pacific Ocean, 513
  density from rocket and satellite measurements, 525
  electric measurements in fog forecasting, 1034
  electricity, airborne measurements, 827
  internal boundary layer, 1048
  pressure and sea-surface temperature in the north Pacific Ocean, 542
  pressure variations, measurement with the microvariobarograph, 366
  radiation, 514
  structure in and around Bahaman cumulus, 512
Atomic bomb, precipitation scavenging from clouds, 60
Atomic bomb, diffusivity of clouds, 58
Audit, fiscal year ending June 30, 1957, 152
Audit, fiscal year ending June 30, 1958, 1194
Aurora, electron and ion fluxes, 512
Aurora-producing particles, origin and acceleration, 510
Auroral program, IGY, 596
Auroral storm of February 10–11, 1958, 1225
Back *Transactions*, reprinting, 352, 574, 993

Baltic States, regional conference on the study of, 131
Beach, the equilibrium, 889
Bibliography
  General, 131, 339, 543, 742, 981, 1173
  Geodesy, 132, 340, 544, 743, 981, 1173
  Geomagnetism and Aeronomy, 133, 341, 545, 744, 982, 1174
  Hydrology, 136, 346, 549, 750, 986, 1178
  IGY, 783, 806, 1025, 1215, 1232
  Meteorology, 134, 343, 546, 746, 984, 1176
  Oceanography, 135, 344, 548, 747, 985, 1176
  Seismology, 137, 346, 550, 751, 986, 1179
  Tectonophysics, 140, 348, 552, 753, 989, 1180
  Terrestrial Magnetism and Electricity, 133, 341, 545, 744, 982, 1174
  Volcanology, Geochemistry, and Petrology, 137, 347, 551, 751, 988, 1180
Biological and medical sciences, 1217
Boundary layer, atmospheric internal, 1048
Bowie Medal
  twentieth award, 385
  twenty-first award, 1200
British Columbia, lead isotope studies of deposits in East Kootenay district, 535
Budget report for the fiscal year ending June 30, 1958, 155
Budget report for the fiscal year ending June 30, 1959, 1192
By-Laws
  notice of intent to change, 766
  suggested amendments, 764

C^{14}/C^{12} ratios in fresh-water systems, 509
Calcite crystals and aggregates, recrystallization 517
California
  eddy diffusion in Santa Monica Bay, 542

  effects of fire on stream flow watersheds in central Sierra, 541
  evaporation study at Silver Lake, Mojave Desert, 1163
  Imperial Valley sky temperatures, 966
  Institute of Technology, progress report of Seismological Laboratory, 721
  land subsidence in western San Joaquin Valley, 541
  nocturnal ground inversions in winter, 542
  rainfall intensity and topography, 15, 970
  shallow ground water and tile drainage in Oxnard Plain, 1101
Cambridge pendulum apparatus, results in North America, 729
Canada
  calibration standard for gravimeters, 195
  dominant flow in the Strait of Belle Isle, 505
  gravity measurements, 615
  rocket results at Fort Churchill, 778
Carbon 14, use as a tool in meteorology, 524
Ceilings, indirect method of estimating frequencies, 533
Channels, straight, secondary currents, 1085
Characteristics of great storms, 124
Circulation, anomalies related to tropical storms, 505
Clays and clay minerals, 131
Climatological problems of circulation of Arctic, 40
Cloud droplets
  growth and collection efficiency, 521
  laboratory measurements of growth, 511
Cloud seeding, cloud duration as an important parameter, 508
Colorado uranium mineralizations, new isotopic data, 525
Composition of the outer core, 524
Compressibility and temperature of the Earth's interior, 943
Compressional waves in Indian rocks, 711
Conditioned observations, adjustment with unknowns, 520
Conductivities of rocks, thermal, measurement by divided bar apparatus, 1111
Conductivity and length relationships in heat-flow transducer performance, 1089
Conductivity, thermal, probe for measurement of frozen soils in place, 730
Conference on educational and professional standards, 1197
Connecticut, flood of August 1955, 1
Continental triangulation distortion, 536, 819
Continents, geophysical and geological study, report of committee, 492
Continents and mountains, hypothesis of formation, 129
Core, chemical composition, 524
Core of the Earth and the magnetic field, 522
Coriolis force, effect on edge waves, 520, 528
Cosmic-radiation phenomena, solar-geophysical aspects, 532
Cosmic-ray
  balloon experiments, 377
  intensity variations, 585
  production, and magnetic fields 532
  program, first twelve months, IGY, 1004
Critical wind velocity for air-sea boundary processes, 335
Cruise of the *Brown Bear*, 363
Crust and upper mantle, composition, 507
Crust, velocity distribution, 528
Cumuliform clouds
  droplet charge, polar conductivities, and potential gradients, 503
  size and electrification of droplets, 527
Currents, secondary, in straight channels, 539
Cylindrical probes, measurement of thermal conductivity and diffusivity, 708

Darcy formula, theoretical derivation, 702
Dating peridotites and intrusive serpentinites, 534
Deep-sea sedimentation rates, 509
Deep-space probe, IGY, 1230
Degree-day snow-melt ratios, 681
Degree days, methods of computing, 529
Densities and temperatures inferred from satellites, 531
Density of basic rocks at high pressures, 959
Depth recorder survey of western Long Island Sound, 505
Dew-point, max-min hygrometer, 63
Diffusion in granular deposits, 67, 1160
Diffusion of SO_2 from a continuous point source, 514
Discontinuity, Mohorovicic, 947
Disposal of radioactive waste on land, 467
Divided-bar apparatus, measurement of thermal conductivity, 505
Downwind Expedition, 528
Drainage profiles, 689
Drainage and water supply in semi-arid countries, 736
Drifting Station Alpha, 1213
Droplet charge in supercooled orographic cumuliform clouds, 503
Droplets in cumuliform clouds, size and electrification, 527
Dunes in streams, 539

Earth's mantle, velocity of seismic waves, 486
Earth satellites, ionospheric studies, 169
Earth Sciences Division of NRC, report for 1956–1957, 156
Earth-strain measurements in South America, 380
Earthquake, Alaskan, of April 7, 1958, 941
Earthquakes and microseisms, correlations, 526
Earthquakes, tectonophysical significance of fault-plane solutions, 530
Eddy diffusion in Santa Monica Bay, Calif., 542
Educational and professional standards conference, 1197
Elastic medium, direct representation of a disturbance, 519
Elections of officers in 1959, 944
Elevation, utilizing correlation with gravity formulas, 1027
Engineering and geophysics, 387
Epicenters, earthquake, indication of areas of tectonic activity in the United States, 1135
Equator, variations with depth of oceanographic properties in the Pacific, 504, 1055
Erosion and deposition, flood of August 1955 in Connecticut, 1
Erosion problems on western arid lands, 527
Eulerian and Lagrangian correlation, 527

- Evaporation
  - study at Silver Lake in the Mojave Desert, California, 1168
  - suppression, 540
  - suppression by a monomolecular film, 517
- Evapotranspiration estimates from heat-budget measurements, 298
- Evapotranspiration, relation to environment and kind of plant, 972
- Executive Committee, recommended revision of structure, 765
- Explorer I, meteoritic impacts, 513
- Extended forecasting from numerical methods, 526

- Fallout, construction of climatological patterns, 524
- Feldspars, isotopic composition of lead, 510
- Fetch, short, relation to water-wave slopes, 405
- Field crop, evapotranspiration estimates from heat-budget measurements, 298
- Flood
  - August 1955 in Connecticut, 1
  - flows, statistical treatment, 732
  - and forest in the northwest, 504
  - frequency by regional synthesis, 974
- Florida Straits, hydrography, 535
- Florida Straits, interpretation of the transverse component of the geomagnetic electrokinetograph readings, 875

Reconnaissance Study of Erosion and Deposition Produced by the Flood of August 1955 in Connecticut

M. GORDON WOLMAN AND JACK P. EILER

Abstract—A large area in the valley bottoms in Connecticut was inundated by the flood of August 1955. Relative to the total area flooded that part permanently modified by the flow was surprisingly small. Although great in some places, the distribution of these permanent modifications of channel and flood plain was spotty.

Erosion of the channel and valley bottom appears to have been most severe in narrow, steep valleys. Environments of deposition were diverse. They appeared to be related to rate and direction of flow, quantity and size of sediments locally available, and in some cases to the presence of vegetation. Most of the coarse sediment deposited in the valley appears to have been derived from local sources such as valley walls and terraces composed of glacial outwash and till and flood plains containing considerable gravel. Fine sand predominated in most of the sediment deposited.

Considering the magnitude of the runoff, the quantity of fine sediment transported or deposited by the flood was small. The maximum observed concentration was 473 parts per million in Scantic River at Broad Brook. Newly deposited fine sediments are thin or absent on the flood plains of many valleys which were beneath 20 ft of slow-moving flood waters. The paucity of deposition in such ideal depositional environments also indicates that the flow did not have a high concentration of fine sediments. A number of boulders five to seven feet in diameter were moved by flood waters in reaches in which smaller gravels were undisturbed.

Severe erosion in the uplands was minor. In this reconnaissance we saw little evidence of newly formed gullies and no areas of severe sheet erosion. This was the case in both woodland and pasture land. Large amounts of subsurface flow and relatively unerodible ground are presumed to be responsible for the absence of erosion.

Introduction—During August 1955, parts of the northeastern United States from Maryland to Massachusetts were visited by catastrophic floods. These floods resulted from excessive rainfalls associated with movement of hurricanes through the area. In Connecticut as much as 26 inches of rain fell during the month, 18 inches of it falling in a period of four days. The meteorology and hydrology of these floods is described in reports published by the *U. S. Weather Bureau* [1955] and the *U. S. Geological Survey* [1956].

This report is concerned with the physical effects produced on the natural landscape by these floods. Observations were made during a brief reconnaissance survey of a number of river valleys in Connecticut which experienced severe flooding during this period. During a three- to four-week period shortly after the floods, indirect determinations of discharge were made, and the data discussed here were collected. Figure 1 shows the location of some of the principal valleys studied. To illustrate the physical effects of an extraordinary flood, detailed observations were concentrated in the drainage basin of the Farmington River which experienced its highest flood of record.

Damage to urban structures, highways, or bridges is well documented elsewhere and is discussed here only as it relates to general principles of erosion and deposition in natural areas.

Condition of the upland—Both the quantity of rain and its intensity during 24-hour periods in northeastern Connecticut were extraordinary. However, in the area covered by our reconnaissance survey, we found no evidence of newly formed landslides or gullies, or of hillsides showing the effects of severe sheet erosion. As an example, the headwaters of Bissell Brook, 2¼ mi southwest of Granby are characterized by high relief with slopes up to 35 or 40° covered with hardwood forest, where 12 inches of rain fell on this area between August 17 and 19, 1955, the surface of the ground outside the swath of the stream was un-

FIG. 1 – Map of Connecticut showing principal streams investigated

altered. Heavily grazed hillsides near Granby and Avon showed a similar absence of erosion features. The lack of erosion suggest both a high infiltration capacity and considerable subsurface flow.

In contrast, in the small headwater streams themselves, such as tributaries to Bissell Brook, large cobbles and boulders were moved by flood waters. The channels consist of alternating pools and riffles, successive riffles being 30 to 40 ft apart. During the flood one such stream with a drainage area of 0.23 sq mi, flowed with a depth of about five feet and a top width of approximately 30 ft on a four per cent grade. After the flood had subsided the alternating pools and riffles remained. The clean-swept appearance of the pools suggested that the larger boulders had been displaced across the pool and lodged in the riffle.

Along with the absence of new gullies and landslides, pre-existing paths for concentrating water carried considerable amounts of soil and rubble during the flood. Abandoned roads and drainage ditches appear to have provided efficient runoff channels.

Where such headwater gullies debouched on flat terraces or flood plains within the larger valleys, they deposited the familiar debris fans. Boulders and cobbles in great quantity were transported by Thorp Brook near Roosterville, Mass. and deposited on a terrace adjacent to the West Branch Farmington River. The size of the material and details of the flow are given in Table 1. Similar debris fans associated with pre-existing channels or gullies were observed on the Quinebang River north of Quinebang and on the Farmington near Napaug Reservoir.

Channel widening—Figure 2 shows six cross sections beneath cableways at gaging stations of the U. S. Geological Survey on streams having drainage areas between 76 and 630 sq mi. Some cross sections are shown prior to the flood of 1938 as well as subsequent to that event in order to eliminate changes which might have been associated with previous high water rather than with the present flood. Despite the magnitude of the flood, none of these sections shows evidence of widening by the flood of August 1955. Although they provide at best, a meager record, the fact that they are well documented perhaps gives them added significance.

The bankfull channel of Bissell Brook near Granby, a typical small stream, is approximately ten feet wide and two feet deep. During the flood, water flowed four to five feet over the surface of the flood plain. Despite the quantity of water and the velocity of flow (sufficient to move a quartz boulder 0.7 x 0.5 x 0.5 ft) during the flood, the permanent channel was left largely undisturbed. This may result from the fact that during this high flood a large percentage of the discharge passed over the flood plain rather than through the main channel.

In contrast, considerable widening of the channel of Lewis Atwood Brook took place near Wood bury, Conn. Widening here appears to be related to

TABLE 1 – *Size of boulders moved by flood waters and some conditions of flow*

River and location	Size of boulder	Drainage area	Flood discharge	Slope	Estimated velocity	Depth of flow	Median size of bed material	Composition	Evidence of movement
	ft	sq mi	cfs		ft/sec	ft	ft

[a] Discharge estimated from drainage area-discharge relation for flood of August 1955.

[b] Estimated

deposition by the flood of coarse boulders which forced the flow against the channel banks.

In narrow valleys where one of the channel banks may be the valley wall, a different type of channel widening occurs. Erosion of such valley walls and associated channel widening occurred in several valleys inspected by us.

Along the west bank of the Farmington River between Burlington Brook and Unionville the river removed several miles of highway and railroad track paralleling the stream. Several weeks after the flood the right bank of the stream had already been pushed back to its former position by placement of a new highway fill. Many locations in Naugatuck valley experienced similar bank erosion within relatively narrow valleys.

Care is often required in interpreting the observations of widening produced by erosion of either natural or man-made valley walls. Widening along the Farmington River, for example, is most pronounced on the outer or concave banks of the channel. Where the flow at such points impinged upon a man-made fill, the channel was temporarily widened. It is quite possible that if the embankment were not replaced after each flood the stream would permanently occupy its new position and readjust its width by depositing on the opposite convex bank. The presence of the embankment, then, which is continuously maintained against encroachment by the river, forces the stream to occupy both a narrower channel and a position toward the convex bank which it might not occupy under natural conditions.

Erosion of steep valley walls of glacial till and outwash adjacent to the stream channel of West Branch Salmon Brook between East Hartland and West Granby was particularly severe (Fig. 3). The mean velocity in parts of this reach was on the order of seven feet per second (Table 1). Confined flows 10 to 15 deep reach well up on the valley

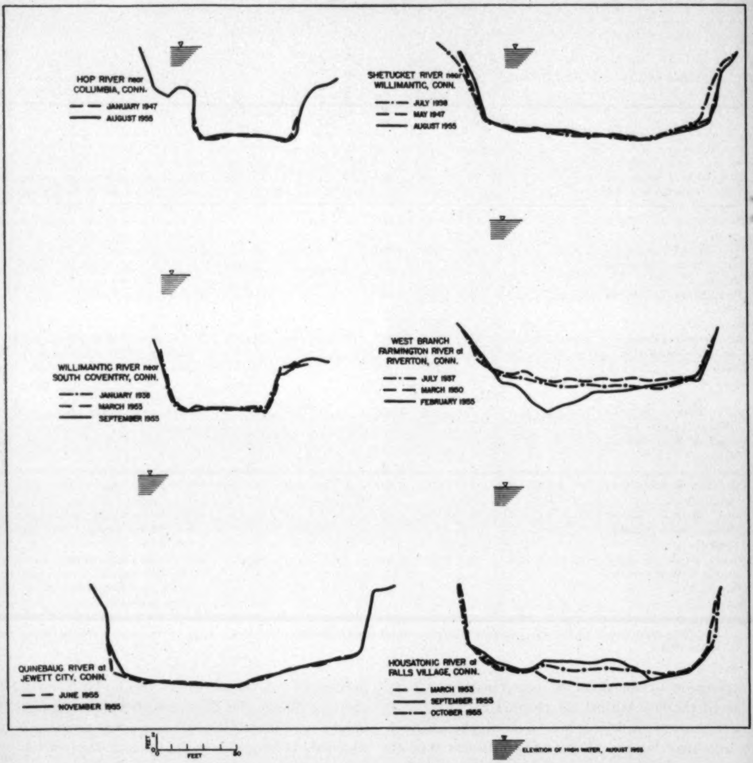

FIG. 2 – Cross sections of channels at cableways before and after flood of August 1955

walls producing severe erosion. The river washed out four or more bridges in this reach alone, and in places removed a vertical slice of sediment of ten or more feet thick from the walls. Because of the instability of the high cut banks the increased channel width will probably not be permanently maintained.

Limited data and observations indicate that in general this flood did not produce extensive widening of channels in broad flood plains. In contrast, however, lateral erosion by this catastrophic flood was especially demonstrable in narrow valleys where the channel width was materially, if only temporarily, increased by the flood.

Channel deepening—Although there are fluctuations in the depth of the channels at specific points, of the streams shown in Figure 2 for which we have the most accurate data, only the West Branch Farmington River at Riverton deepened its channel significantly during the flood. At the Housatonic at Falls Village, several feet of sand was deposited on the coarser bedded channel. As the cross sections show (Fig. 2) subsequent lesser flows are progressively removing this finer material reestablishing the former bed level. The data also indicate that at some sections, fluctuations in depth produced by moderate flows and annual floods subsequent to 1938 and prior to August

1955, were as great as or greater than those produced by this record-breaking flood.

Some evidence is also available on deposition and scour resulting from the large flood in data obtained by the U. S. Geological Survey at gaging stations. For a given discharge the stage of the flow is governed by a control which may be a gravel bar or riffle, downstream channel reach, or perhaps a concrete sill. If a control is scoured during a flood, the gage height previously associated with a particular discharge will now be associated with a larger one. On the other hand, if the channel experienced a net fill as a result of the flood, then one should expect the reverse. Although the data in Table 2 are of limited value because many of the controls are not readily altered by the flow, shifts in control which took place during the flood of August 1955 are interpreted in terms of scour and fill.

Of the gaging stations in Table 2 having relatively natural controls, about half show neither scour nor fill. Filling is indicated at all of the controls which experienced changes. Other cross sections studied in detail did not show a net scour and thus could not represent typical sources for the net fill experienced at some of the gaging stations. It may be concluded that (1) the material was not derived from the channel bed, or (2) the amount of material moved was relatively small. This view is supported by the small amount of material deposited on the controls. Because no change took place at more than half of the stations considered, we cannot conclude that either scour or deposition occurs universally in the river bed during or after the flood.

Documented cross sections present little evidence of major channel deepening resulting from floods. Local rearrangement of bed material produced some deposition on previously existing riffles or rises in the channel bed. These data indicate that the flood did not alter a large proportion of the natural river channel. In places this lack of change may be related to bypassing of the main channel by the high water. Elsewhere the controlling factor may have been the inability of the flood flow to erode armored beds of gravel, even of sizes as small as ¾ inch (see below).

FIG. 3 – West Branch Salmon Brook near West Granby, Conn. showing erodible valley wall and large boulders moved during flood; valley bottom is 70 feet wide; note man to left of center of figure.

Detailed descriptions of deposition and erosion on flood plains and terraces—To aid in attempting to understand the processes producing the complex distribution of erosion and deposition in valley bottomlands during a flood, reaches in two valleys which were struck by the flood are described in detail. These represent extremes in the degree of alteration produced by the flood and thus are not representative of the changes wrought over the inundated area as a whole.

Two cross sections were made on the right bank and flood plain in a curving reach of the Farmington River opposite the mouth of Cherry Brook, 1½ miles north of Collinsville, Conn. (Fig. 4). The river here has a drainage area of 350 sq mi. Profiles of the land surface prior to the flood were

FIG. 4 – Cross sections of flood plain and terrace levels on Farmington River at Cherry Brook, Conn. following flood of August 1955

determined from holes dug at closely spaced intervals across the section. Section AA is 100 ft downstream from the mouth of Cherry Brook. Section BB is 500 ft upstream. At the peak of the flood, water flowed 12 to 20 ft deep over the entire area.

Although section AA traverses a relatively open area of the flood plain largely covered by grass, while much of section BB is more forested, several comments are common to both of them.

(1) There are two distanct levels in each section. The lower, presumably the active flood plain adjacent to the stream channel, is approximately seven feet above low water. The upper surface or terrace is approximately ten feet above low water (see Table 3).

(2) Considerable differences in elevation existed on the flood plain caused by the presence of overflow sloughs or channels prior to the flood. Differences of elevation of three to five feet over lateral distances of 20 ft were common.

(3) Some of the overflow channels or sloughs received deposits of coarse and medium sand to depths of one foot. At such locations the relief was materially reduced. In general, the flow appears to have followed these former overflow channels and hence to have maintained the preexisting surface relief.

(4) No deposition took place at many points in cross section *AA*, and at some points in section *BB* (Fig. 4). A veneer of sand often gives the impression of more deposition than actually occurred.

(5) The new deposits consist principally of well sorted medium and fine sand. It is worth emphasizing that all of these are unusually well-sorted alluvial deposits (Table 4). Although sorting is somewhat poorer in the underlying sediments, in

[a] All in Connecticut.

both sections *AA* and *BB* the flood deposits are similar to the underlying material (Table 4). Those differences that do exist are not consistent from one sample location to another.

In section *BB* a maximum thickness of 37 inches of sand was observed at station 200. Deposition in section *BB* exceeded that in *AA*, while farther upstream from *BB* a blanket of sand was deposited by the flood.

The larger volume of material deposited at section *BB* is perhaps attributable to the forest vegetation although the woodland is relatively open and the ground cover primarily grass. It is also possible that the thicker deposit at section *BB* is related to the direction of flow during waning stages of the flood when section *BB* perhaps was a locus of deposition on the convex side of the bend.

An average of about one foot of sand was deposited in a cornfield (section *BB*, Sta. 400–520). Inasmuch as the stalks remained upright this deposit may be attributed to the trapping effect of the corn. Perhaps of equal importance, however, was a wooded spur of high ground protruding into the valley upstream which reduced the velocity across the field below.

These sections on the Farmington River at Cherry Brook indicate that as one might expect pre-existing topography, relative orientation of valley and flow, vegetation, and composition of available sediment all played a part in determining the conditions of deposition and scour resulting from the flood.

Figure 5 is a cross section of the West Branch Salmon Brook 2.2 miles southwest of Granby, Conn. The drainage area at this point is nine square miles. Prior to the flood the main channel flowed through a moderately dense forest cover to the left at station 600. At the peak of the flood, water flowed approximately three feet deep over the entire section. When floating trees and other debris partly blocked the main channel at the upper end of the reach the water, seeking an

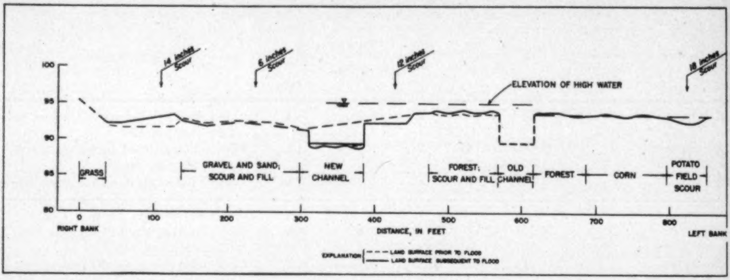

FIG. 5 – Cross section of West Branch Salmon Brook near Granby, Conn., following flood of August 1955

alternate course across the flood plain and terrace, eroded a new channel approximately 3½ ft deep and 80 ft wide (Fig. 5).

The new channel cuts across the chord of a bend but is not a typical meander cutoff inasmuch as the new channel leaves the old at an abrupt angle. Although large trees obstructed the flow, their effectiveness was enhanced by the presence of boards and fragments of old wooden structures. Such a cutoff is a natural and repetitive occurrence but not a predictable one. Although similar ones took place elsewhere, our observations indicate that permanent cutoffs produced by the flood were the exception rather than the rule. The effects of the flood on the West Branch Salmon Brook are best described by referring to the cross section (Fig. 5).

The lower part of the stratigraphic section through the flood plain exposed in the channel bank contains coarse gravel overlain by fine sand and silt. The contact between the two is exceedingly irregular. In some places gravel lies within a foot of the old surface; elsewhere it is two to three feet below the surface. The pre-flood surface of the flood plain was eroded as much as a foot in places (Fig. 5). At these points fresh gravel was deposited by the flood subsequent to the period of scour rest upon older gravel in the flood plain. Elsewhere fresh cobbles and gravel were deposited on top of the finer sediments of the flood plain. The contact between the older sediments and the newly deposited sand and gravel lies from about one foot to six inches below the pre-flood surface of the plain. The original surface at station 460 is about 1.5 ft higher than the contact. Thus the gravel-capped area on the right bank of the new channel is predominately one of scour.

In contrast to the reduction of relief observed on the Farmington River, between stations 480 and 570 (Fig. 5) differences in elevation on the flood plain were increased by the flood. This came about through deposition of parallel ridges of sand aligned in the direction of flow with alternating swales between them produced by moderate scour. Farther to the left of the old channel scour was particularly severe along rows of potatoes parallel to the overflow.

Limited deposition of sediment along Farmington River between Farmington and Tariffville—The preceding description emphasized the extreme alteration produced by the flood in West Branch Salmon Brook and Farmington River at Cherry Brook. Contrasting conditions are perhaps illustrated by the following observations in the Farmington River valley between Avon and Tariffville, Conn. Shortly after the flood, parts of the valley which had been beneath 20 ft of water appeared to be virtually unaffected by the flood. Indeed in many areas four weeks after the event, it would have been impossible to tell that the area had been flooded save where houses and other works of man showed clearly the damage produced by inundation. To test these impressions in one valley a reconnaissance survey was run.

Between Tariffville and Avon, a distance of 7.5 mi along the river valley, 3.4 sq mi of land had been inundated. The area of inundation was roughly determined by planimetering on a topographic map. Each linear mile parallel to the valley included on the average 0.45 sq mi of flooded area. In each segment along the valley by observation or examination we estimated the percentage of the area covered by sediment and the thickness of the deposit. The length of the segment was determined from odometer readings. To compute the area covered by sediment the odometer mileage was multiplied by the average area inundated per linear mile of valley, and this product was multiplied by the estimated percentage of the area observed which was covered by sediment.

At a few localities we examined the deposits in detail. The estimates of thickness of very thin deposits are obviously rough. This is particularly true in areas in which no deposition is reported. In such places it is conceivable that a thin veneer of sediment of the order of less than 0.02 foot which was not distinguishable at the time of the survey may have existed. The following results are put forth with this qualification in mind.

Deposition appears to have occurred on 15 pct of the 3.4 sq mi inspected in the Farmington valley. Of this 15 pct, about 25 pct was estimated to have been covered by a thickness less then 0.05 foot of sediment and approximately 16 pct by a thickness of 0.1 foot or greater. Thus, not only was the area of deposition small but within the area the deposit is exceedingly thin. Because of the spottiness of the deposits, computation of a figure for the average thickness of deposition over the entire valley would not be justifiable. The relation of deposition to conditions of flow is illustrated in more detail by the following examples.

Near Farmington, Conn. the Farmington River makes an abrupt bend turning from southeast to north (Fig. 1). At this bend the valley is approximately 1.5 mi wide. During the flood the valley was inundated to a depth of 18 ft. The gradient of the river determined from a topographic map is only 0.0001. It is not surprising that in this ideal setting basin there was a deposit of silt (Table 4, sample 10) as much as one foot thick. Less than one mile upstream, however, inundation occurred to similar depths (see Fig. 6) and despite the low gradient, wide valley, and depth of inundation, the area shows little or no effects of flooding (Fig. 7). The 'untouched' look of the flood plain is remarkable. It was described in our reconnaissance survey as an area of no deposition.

On the left bank of the Farmington River one mile upstream from Route 44 near Avon, Conn., the high-water mark on a barn is 19 ft above the level of the plain. Most of the area several weeks after the flood appeared untouched. In places scour was evident around the roots of corn and thin veneers of silt were observed adjacent to these points of scour. Despite such minor changes, the over-all aspect of the flood plain appeared unchanged by the flood.

Our observations of the Farmington valley suggest: (1) The total amount of sediment deposited by the flood was small. (2) Considering the ideal depositional environment provided by the flooded valley, one must conclude that the flow carried only a small concentration of sediment. The absence of erosion on the land gives weight to this conclusion. (3) The areas in which deposition took place are predominantly shallow depressions. (4) The thickness of the deposits where they occur is generally less than 0.05 foot.

Measurement of suspended sediment; Scantic River at Broad Brook—Suspended sediment is measured at only one station in the area flooded in Connecticut. Because water overtopped the bridge and sampling device on Scantic River at Broad Brook the record is incomplete. Nevertheless, the selected data in Table 5 show the range and fluctuations in concentration observed at specified times during the flood. (The complete record is published by the U. S. Geological Survey in annual reports, on Quality of Surface Water of the United States.)

The peak concentration on Scantic River occurred prior to the peak discharge. Although concentrations observed in this flood somewhat exceed the selected values observed in several other high

flows (Table 5) the maximum measured concentration of 473 ppm associated with a discharge of 392 cfs is not high. The moderate concentrations observed perhaps support the conclusions arrived at indirectly from observations of erosion and deposition in the Farmington River valley.

The data in Table 5 clearly show the abrupt fluctuations in concentration associated with the flood. In a period of three hours on the afternoon of August 18, despite a continuously rising discharge, the concentration of the measured sediment dropped by a factor of 20. Such changes are probably related to differences in the distribution and intensity of rainfall but adequate data are not available for analysis.

Table 6 shows the size and sorting of the suspended sediment. The suspended material is roughly 10 to 20 times finer than the flood deposits (Table 4). The flood deposits are unusually well sorted whereas the suspended sediment is quite poorly sorted.

Competence of the flood—Table 1 is a compilation of the sizes of boulders moved by the flood in channels having different discharges, slopes, velocities, and depths. The evidence of movement consisted of boulders overlying vegetation, or resting upon signs or tin cans, or of reports of local observers living adjacent to the stream who could identify with certainty the former position of the boulder in question. In the latter case the former position of the boulder could often be verified by the water mark on its surface or by a gap at the position which it formerly occupied.

The sizes of the boulders are the dimensions of three mutually perpendicular axes. The slope in most instances was derived from the topographic map. Where available the velocity is the mean velocity of the flow determined as the quotient of the discharge divided by cross-sectional area. The discharge, unless otherwise noted, is based on indirect determinations of the *U. S. Geological Survey* [1956]. The median diameter of the bed material was determined by pebble counts.

Some phenomenally large boulders were moved. The largest boulder of which we have a verifiable record is a nine-foot granite boulder moved by the flood in the East Branch Naugatuck River. The slope of this stream is steep and judging from the mean velocity, point velocities of 15 to 18 ft per second may well have existed in the flow.

Individual boulders moved by the flow were often large in comparison with the median size of the bed material (Fig. 8). Boulders two to eight times as large as the median size on the bed were moved in reaches where the median material did not move. In the Farmington River at Unionville, the presence of moss and algae covering the average size cobbles on the bed indicates that this smaller material was not moved by the flow, while boulders many times larger were moved over the gravel. The 'armored' character of such gravel beds has often been noted in the literature.

The fact that large boulders moved under conditions in which smaller stones did not suggests that a parameter relating the size of particle moved to the average of the material making up the bed, such as *Ippen* and *Verma* [1953] used in determining criteria for movement, may be particularly useful in dealing with transport of large particles in natural rivers.

Relation of flood stage to elevation of deposits—In West Branch Salmon Brook sand and even gravel were deposited on a terrace surface approximately seven feet above the bed of the channel. The high stages reached by a flood of this magnitude permit deposition at elevations well above the reach of the annual flood. *Jahns* [1947] has described such aberrant deposits which interrupt the depositional sequence in the flood plain and on top of the higher terraces.

Roughly three alluvial surfaces are indicated by the data from random valley cross sections given in Table 3. The lowest is at an elevation of about two to four feet; the next lies between 8 and 12 ft, and the highest surface in these cross sections lies somewhere between 18 and 23 ft. In most places the large flood of 1955 inundated both of the lower levels. In general, despite two to five feet of water over the 8- to 12-foot level, deposition and erosion on this surface were moderate. In some places, as for example on the 13-foot terrace remnant of the West Branch Farmington River at Pleasant Valley, there are scour holes several feet deep immediately adjacent to which are sand splays as much as a foot thick.

Jahns [1947] has established the fact that the floods of 1936 and 1938 in the Connecticut Valley in Massachusetts attained stages in excess of any of those in recorded history or in recent geologic past. This conclusion can probably be safely applied to the areas inundated in Connecticut as well. It has been established that the flood of August 1955 considerably exceeded the peaks attained by the 1936, 1938, and 1949 floods in the valleys described here [*U. S. Geological Survey*, 1956]. In a few valleys the stage was sufficiently high to result in deposition or scour on terrace surfaces not reached by previous high water.

Source and compositions of deposits—The town of Unionville, Conn., was devastated by the Farmington River during the flood. Where the current impinged upon the left bank of the river near Route 4 in Unionville, numerous houses were undercut and swept down the river. Where these houses stood, only a cleanly washed cobble and boulder terrace remains. This terrace, 11 ft above low water, corresponds to similar terrace elevations observed elsewhere in the basin (Table 3). Although the gravel appears to be a new deposit, its elevation suggests that a layer of material was removed from the surface of the existing terrace with small displacement of the terrace itself. Several hundred yards downstream sand was deposited on the flood plain. Inasmuch as trees eight inches in diameter were uprooted by the flow which local residents estimate had a velocity at the peak on the order of 20 mi/hr, deposition apparently took place on the falling stage of the flood. The small quantity of sand deposited suggests that the scoured terrace immediately upstream was a likely source for the sand.

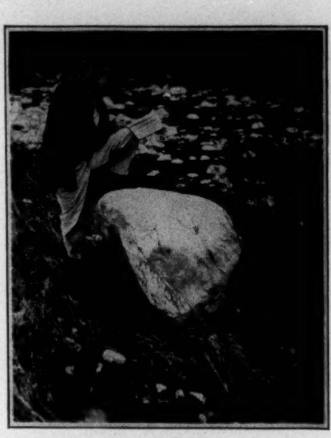

FIG. 8 – Boulder moved by flood of August, 1955, West Branch Farmington River near New Boston, Mass.; note smaller size of median bed material

Extensive deposition occurred on the flood plain of the Farmington River at River Glen. The swept angle of the trees as well as the removal of several houses testifies to the strength of the current. Banks of glacial outwash upstream below Unionville, eroded by flood waters, appeared to have provided the source of the deposit of coarse sand (Table 4, sample 9).

Several possible sources exist for the gravel deposits previously described at West Branch Salmon Brook near Granby: (1) gravels within the flood plain itself, (2) steep and readily erodible bank of sand and gravel 300 feet upstream, and (3) the severely eroded valley section (Fig. 3) three miles upstream. The intense scour of the pre-flood flood plain, the absence of coarse particles in the channel bed at the foot of the exposed bank, the absence of gravel and cobbles in the overflow section above the potato field, and lastly, deposits of sand and gravel in scour holes in the potato field apparently derived from the holes themselves,

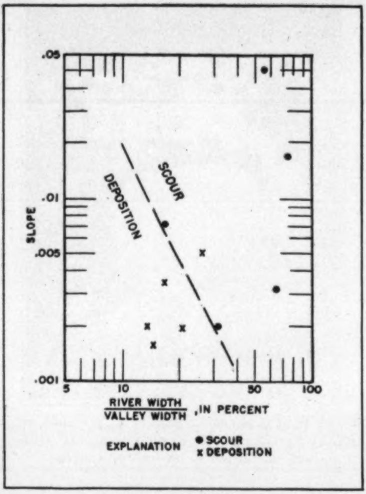

FIG. 9 – Conditions of deposition and scour related to slope and ratio of river width to valley width

suggest that again the deposits were locally derived.

Many man-made embankments and highway approaches were washed out or destroyed by the flood. In almost every case the material derived from these bridge approaches can be seen strewn out several feet below its source in the eroded fill. Good examples of this were observed by the authors on the Pomperaug River at Southbury, Conn., on French Creek near Putnam, on Willimantic River near South Coventry, and on Bissell Brook near Granby. In most instances it appears that local sources provided the bulk of the material deposited on the flood plains and terraces.

Factors controlling erosion and deposition by flood waters—In several reaches where either scour or fill was particularly evident, data were obtained on slope and relative width of channel and valley. In most cases slope and valley width were measured on topographic maps. The channel width was determined by measuring or by pacing. The meager data are plotted in Figure 9 simply to illustrate, as graphically as possible, any existing relationship.

The graph indicates that in general scour is related to steep slopes and narrow valleys. It appears that at a given slope where the channel is roughly from ⅕ to ⅓ of the valley width, there was a tendency for scour rather than deposition. Inasmuch as steep slopes and narrow valleys, which are associated in nature, both contribute to increased velocity and depth at a given high discharge, it is to be expected that such conditions would produce a tendency for scour rather than fill.

Direction of flow—Numerous sites were seen in the field at which the direction of the flow relative to the orientation of the valley as a whole exercised a controlling effect on conditions of sedimentation. One such case from the Quinebaug River is described below.

The dimensions and flow characteristics of an upstream and a downstream cross section of the valley of the Quinebaug River near Quinebaug, Conn., are given in Table 7. The sections are about 800 ft apart.

At the cross section upstream the flood scoured a channel six feet deep and 15 ft across, extending downstream about 200 ft from the narrowest section of the valley. The material eroded from the flood plain was deposited at the downstream end of this scoured channel.

As the flood flow expanded into the larger reach downstream, conditions of scour and deposition changed. Adjacent to the left bank of the channel there is an area of continued scour, although at the reduced velocity the flow was not sufficient to scour a major cut as it did upstream. Proceeding from this area of scour toward the left edge of the valley, the environment changed from one of scour to one of deposition. The sediments deposited by the flood become progressively finer to the left (Table 4, samples 11, 12, 13). The cross-sectional area of the upstream section is about one half of the downstream section (Table 7). If the flood discharge (*U. S. Geological Survey*, 1956] was evenly distributed in each of these cross sections, the mean velocity in the upstream section would be approxi-

TABLE 7—*Estimated flow conditions in cross sections on Quinebaug River near Quinebaug, Connecticut*

Cross section	Discharge	Total width of valley cross section	Total Area of valley cross section	Average velocity in cross section discharge area
	cfs	ft	sq ft	ft/sec
Upstream	49,300	430	4,900	10
Downstream	49,300	630	7,662	6

mately ten feet per second, while the mean downstream would be six feet per second. The high velocity is associated with scour. On the other hand, the 'mean' velocity at the downstream section is obviously not descriptive of conditions at different points across the valley. Judging from the scour adjacent to the channel, the main flow moved along the right edge of the valley. The flow expanding toward the left margin, however, appears to have had a different orientation and a much lower velocity. Those areas in which the flow diverged most markedly from the main current received the deposits of finest texture.

The irregularity of most valleys provides numerous local sedimentary environments. A large part of the flood flow may travel across a valley floor as a swiftly moving mass, while on either side of it the flow is virtually motionless. A protruding spur may force the main current to move obliquely across the valley producing a separation of flow and a quiet eddy in the lee of the spur. Thus orientation and direction of flow account for much of the diversity in sedimentation produced by a large flood.

Effect of vegetation—On the Farmington River at Cherry Brook, one foot of sand was deposited in a cornfield. On the flood plain of the Farmington near Avon, scour rather than deposition characterized the cornfield. On the Quinebaug River in the downstream section the cornfield was the site of both scour and deposition (Table 4), depending upon the lateral position within the valley. In addition, although the cornfield was scoured, deposition took place on the grassed areas (Table 4) which might have been expected to trap much less sediment. Similarly, on the left side of the upstream cross section of the Quinebaug River, despite little change in the density of the forest cover, three inches of sediment was deposited near the left margin of the flow while 100 ft toward the center of the flow no deposition or scour was observed within the forest. Here again the position of each point relative to the flow rather than the vegetation controlled the amount of deposition.

The effect of forest vegetation in inducing deposition was more clearly seen on an island near the center of the flow of the West Branch Farmington River, one mile south of Riverton. The small island supports a growth of deciduous and evergreen trees many of which are one to two feet in diameter, spaced approximately 10 to 20 ft apart. One inch to two feet of course and medium sand was deposited beneath the trees while in the channel adjacent to this tree-covered island, the flow was approximately 20 ft deep and moved boulders one foot in diameter.

It is difficult to generalize regarding the effect of vegetation on sedimentation during a flood. Other things being equal, that is, for example, where slope, valley width, and direction of channel flow are the same, deposition appears to be aided by vegetation. There are, however, many locations in the average stream valley where these other factors far outweigh the effect of the vegetation in controlling positions of scour and deposition.

Effect of changes in river stage—We observed one locality at which the sediments deposited by the flood provide some evidence of the effect of changing stage on flood deposition. On a seven-foot terrace adjacent to West Branch Salmon Brook near Granby (Fig. 10) six inches of cobble gravel were deposited on the old surface, and upon the gravel an additional 6 inches of course and medium sand was deposited. Their successive positions as well as the sharp contact between the two suggests that the gravel was transported at a high stage and velocity and that the sand was deposited later during recession of the flood.

Acknowledgments—We are indebted to L. B. Leopold for his assistance in the field, to B. L. Bigwood, District Engineer, Hartford, Conn., and to members of his staff. Personnel of the Surface and Quality of Water Branches of the U. S. Geological Survey provided us with much information regarding the flood. Both the *Hartford Courant* and the *Hartford Times* very kindly put at our disposal their extensive files of photographs of the flood. It is a pleasure to express our appreciation for this service.

Correlation of Rainfall Intensity and Topography in Northern California

RAY K. LINSLEY

Abstract—As part of a long-range program on the hydrology of small watersheds, a correlation between the two-year, one-hour rainfall intensity at 126 recording rainfall stations in northern California and related topographic and climatic parameters has been made. The resulting correlation has a coefficient of correlation of 0.88 and a standard error of 0.067 inch/hour. With this relation, it is possible to show the variation of rainfall intensity over the area in much greater detail than has hitherto been possible from observed intensity data alone. This paper discusses the parameters employed, the methods of correlation, and the results obtained.

Introduction—One of the problems in any study of rainfall intensity is the limited number of stations with record suitable for frequency analysis. For a regional study, data are limited to the hydrologic network stations available since about 1940. After preliminary study, it was decided to limit this analysis to California north of 35° N to avoid introducing large scale climatic factors. In this area approximately 150 station records were available for use. After screening to eliminate records which were too short or were composites from several station locations the number was reduced to 126.

The maximum length of record was ten years and the average length substantially less. Consequently the two-year, one hour intensity was adopted as the best choice of a dependent parameter. Since clock-hour data were readily available, these were used although the maximum 60-min values would be somewhat higher. Occasional summer thunderstorms produce high-intensity rains in California. Because these storms are the result of quite different meterological processes, they were excluded from the analysis by using only the September through April period. Since most of these summer rains fall on dry ground and produce little runoff, this exclusion does not seem to affect the utility of the results.

The general technique utilized is that previously employed by *Spreen* [1947] *Burns* [1952], and others for relating mean annual or mean seasonal precipitation to topography. The coaxial method of graphical correlation [*Linsley* and others, 1949] was employed because of the flexibility it offers. Since a relatively large number of stations was to be analyzed, data were transcribed onto Keysort punched cards. These cards could be easily stratified and average values computed for each parameter as needed.

The complete study [*Linsley*, 1956] involved comparison of four alternative relationships. This paper reports only the one which seems to offer the best results.

Index daily rainfall—It is a logical assumption that, within a small region where the occurrence of rainfall at all stations is limited to about the same number of hours in a year, hourly intensities will bear some relation to mean annual precipitation. The study area is too large for strict adherence to this assumption and a parameter called index daily rainfall was defined by

$$\text{Index daily rainfall} = P/N_{0.25} \qquad (1)$$

In this equation P is the normal (or average) September through April total precipitation and $N_{0.25}$ is the average number of days (September through April) with rainfall in excess of 0.25 inch.

It is recognized that this is not truly a topographic parameter. Its use in the relation limits estimates of intensity to points where values of P and $N_{0.25}$ are known or can be estimated. It has been shown [*Spreen*, 1947; *Burns*, 1952] that normal seasonal precipitation can be estimated quite well from topographic factors, while values of $N_{0.25}$ can be interpolated quite readily between existing stations. Hence, it is not felt that the adjusted mean daily rainfall factor limits the technique, while its inclusion materially facilitates the subsequent analysis.

Land slope—The rate of formation of precipitation is materially influenced by the rate of lifting of the air. Several indices of land slope were tested. The definition finally adopted is given by

$$\text{Land slope} = \bar{E}_{\mathrm{NE}} - \bar{E}_{\mathrm{SW}}/50 \qquad (2)$$

where $\bar{E}_{\mathrm{NE}}$ is the average elevation of the terrain in the northeast quadrant at a distance of 25 mi from the station and $\bar{E}_{\mathrm{SW}}$ is a comparable figure for the southwest quadrant. Both values were computed as the arithmetic average of seven

ZONES OF ENVIRONMENT

FIG. 1 – Zones of environment; the heavy dotted line marks the boundary between zones of homogeneity used by the U. S. Weather Bureau in studies of relations between rainfall intensities for various frequencies

values. The resulting slope figures are a generalized land slope in ft per mi. Data for slope (and similar parameters) were taken from U. S. Coast and Geodetic Survey aeronautical charts.

Elevation—The influence of elevation on rainfall intensity needs little discussion. Actual station elevation as reported by the U. S. Weather Bureau was used for this parameter.

Orientation—In a region where storm winds come almost exclusively from the SW quadrant, the aspect of the slope on which a station is located would be expected to be an important factor in its storm experience. Orientation was defined as the compass bearing (in degrees from *N*) of the centerline of the largest sector of a 20-mi radius circle centered at the station not containing a barrier more than 1000 ft higher than the station location.

This is a discontinuous parameter for which no regular variation in influence may be expected. Hence, stations were classified into intervals varying from 15° to 45° of orientation and inter-

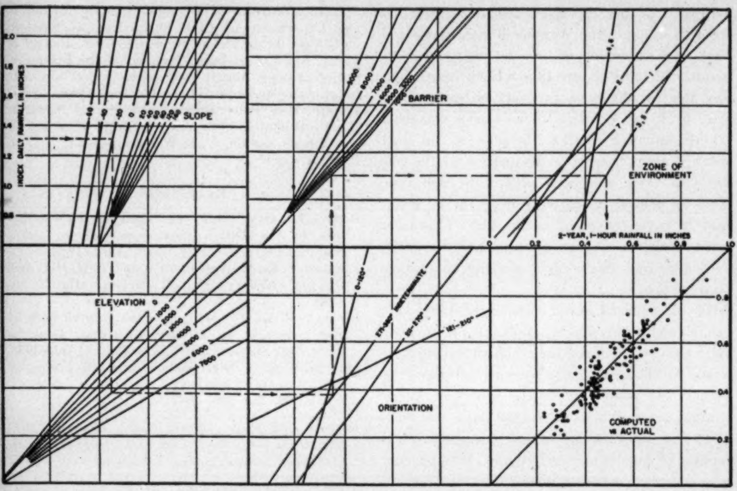

Fig. 2 – Relation between topography and rainfall intensity

polation within the curves is not appropriate. For summit stations without a barrier within 20 mi in any direction and any valley stations completely enclosed by a barrier, the orientation is designated as 'indeterminate.'

Barrier—If the air approaching a station has been forced to rise over a windward barrier, a portion of its precipitable moisture may be condensed and removed by precipitation. Hence, a barrier height was employed as a parameter. The barrier height was defined as the average of the maximum elevations within 45 mi of the station along each of seven rays from the station. The rays were in the southwest quadrant on bearings of 180°, 195°, 210°, 225°, 240°, 255°, and 270°.

Zone of environment—The first correlation developed failed to explain all of the variation in the observed rainfall intensities. Inspection of the residual errors showed some systematic geographical variations. Consequently stations were grouped into geographic zones (Fig. 1) and the zone numbers used as a final parameter. Subsequent refinements permitted combining some of the zones.

The several zones delimit natural topographic regions—mountain ranges and major valleys. This parameter undoubtedly reflects in part the greater frequency of storms in the northern part of the study area. In addition, it certainly represents a variety of topographic and climatological factors not included in the other parameters.

Results—The final relationship is shown in Figure 2. For this relation: standard error = 0.067, average error = 0.051, coefficient of correlation = 0.88, and average bias = +0.001, all based on the 126 stations employed in the analysis.

The relation is applicable to the study area previously defined but should be used with caution outside of this area.

Errors in the relationship may be expected from two causes: (1) inadequacy of the parameters utilized and (2) inadequacy of the basic data. Errors from (1) are those resulting because the selected parameters do not correctly measure the significant causal factors. Undoubtedly better parameters could be found by tedious trials but a significant gain in accuracy in unlikely. Trials in other areas would seem to offer more prospect of productive results than further work in northern California.

Errors in the basic rainfall intensity data used in the study may be quite significant. These 'errors' are not so much mistakes in recording and transcribing the raw data, as the inaccuracy of our estimates of the two-year, one-hour intensities from these data. The Weather Bureau has found that the maximum 60-min intensity averages about 1.13 times the maximum clock hour. Thus any item of the basic precipitation data might vary by 13 pct or more from the true maximum 60-min intensity. Further, because of the short record lengths there is no assurance that the true two-year event has been defined in each case. Thus an analysis based on a longer record might lead to more consistent results, that is, smaller errors. Since these errors are presumably random, such a revision might not materially change the final relation.

The relation of Figure 2 includes the index daily rainfall and thus is directly applicable for intensity estimates only where daily rainfall records are available. This, of course, permits estimates for many more points than are now served by recording gages. Where no rainfall data are available, estimates of mean annual precipitation and number of days of rain are required. It is believed that in many instances these values can be estimated more successfully than could the intensity.

Acknowledgments—This project was carried out in the Department of Civil Engineering at Stanford University under a grant from the U. S. Bureau of Public Roads. Carl Izzard represented the Bureau on project matters. Actual work on the project was done by graduate students: Herbert Osborne, David Crane, Edward Hsia, Peter Binkley, and Marcus Nomikos. Basic precipitation data were supplied by the Cooperative Studies Section, U. S. Weather Bureau, J. L. H. Paulhus, Chief.

Some Results of Geothermal Investigations of Permafrost in Northern Alaska

MAX C. BREWER

Abstract—Frequent, regular thermal measurements in northern Alaska over a six-year period have provided information on many of the problems related to the temperature and distribution of permafrost in the Arctic. The maximum depth of permafrost near Barrow is 1330 ft. The minimum permafrost temperature recorded, below the depth of measurable (0.01° C) seasonal fluctuation (70 to 100 feet), is −10.6° C. The temperature effect of medium-sized (40 by 100 ft) heated buildings resting on permafrost is measurable to depths well below 50 ft. It is doubtful that frozen ground at shallow depths extends outward more than a few tens of feet from the shore of the Arctic Ocean although it may be present at depths greater than 100 ft. Lakes deeper than about seven feet do not freeze to bottom and may have an unfrozen zone approaching several hundred feet in depth beneath them.

Introduction—Thermal measurements made by the U. S. Geological Survey in northern Alaska for the past six years have shown that the thermal regime in permafrost areas is often predictable. (The term permafrost, as used in this report, is defined as material in which the temperature is below 0°C for two to many thousands of years in accordance with the original definition proposed by *Muller* [1947]. Surface features such as engineering structures and bodies of water produce anomalous thermal conditions in the permafrost. Topography, surface cover, and composition also affect the thermal regime of permafrost, but in this paper only areas where these factors could be held held to a minor role are described. Theoretical work on many of these relationships is progressing and will be correlated with the field data in later interpretive studies.

Techniques of observation—Temperature measurements were obtained by freezing multiconductor cables that contain regularly spaced thermistors [*Swartz*, 1954] into the ground or ice and leaving these cables in place. Readings were usually taken weekly, although they have been taken as frequently as every few hours or as infrequently as several months. The accuracy of the measurement of temperature change at any one thermistor is ±0.01°C. The accuracy for all measurements, using an ice-water bath for a standard, is believed to be better than 0.1°C.

Areas studied—The permafrost conditions in the Barrow, Cape Simpson, Umiat, and Shaviovik River areas (Fig. 1), are believed to be representative of those throughout much of northern Alaska. The engineering problems posed by the permafrost are also similar throughout these areas.

The climatological conditions at Barrow and at Umiat are assumed to be representative of the coastal plain and the interior Arctic foothills areas respectively. Barrow has an average annual air temperature of + 10.0°F (−12.2°C) (32 years of record). The freezing index (maximum cumulative degree (°F) days below freezing (32°F) for one freezing season [*Linell*, 1953]) is approximately 8600 and the thawing index (maximum cumulative degree (°F) days above freezing for one thawing season) is approximately 600. The average annual temperature at Umiat (based on six years' record) is 10.1°F (−12.1°C), the freezing index is approximately 9700 (1950–1954), and the thawing index is approximately 1650 (1950–1953). The temperature extremes at Umiat −63°F (−52.8°C) and 85°F (29.4°C) are greater than those at Barrow, −56°F (−48.9°C) and 78°F (25.6°C) largely because Umiat lacks the moderating influence of the ocean.

The Arctic coastal plain, with its many shallow lakes, usually oriented in a nearly north-south direction, is treeless and has very little local relief. The foothills province typically has a gently rolling relief of 100 to 500 ft., fewer lakes, and willows in the major stream valleys.

Depth and temperature of permafrost—The depth of permafrost in northern Alaska varies greatly depending on latitude, length of seasons, surface cover, proximity to the ocean, and the distribution of rivers and large lakes that do not freeze to the bottom.

A maximum depth of permafrost of 1330 ft is indicated eight miles south of Barrow by an extrapolation of the geothermal profile. The maximum measured depth is 1050 ft at Cape Simpson Well 13. The minimum measured depth is 820 ft at Cape Simpson Well 21 which is approx-

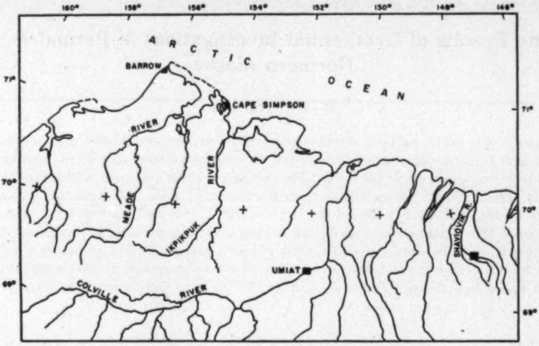

FIG. 1 – Sketch map showing selected permafrost areas studied in northern Alaska

imately 0.9 mile from the Arctic Ocean and is probably affected by the ocean and two nearby lakes.

The temperature profile for Cape Simpson Well 28 (Fig. 2), is typical of deep wells in northern Alaska. The depth of permafrost at this well is 915 ft, and the minimum temperature recorded, below the maximum depth of measurable seasonal change (70–100 feet), is −9.9°C at 140 ft. The lowest temperature recorded at similar depths in northern Alaska (near Barrow) is −10.6°C. This unusually low temperature has invariably been recorded in swampy areas of poor drainage.

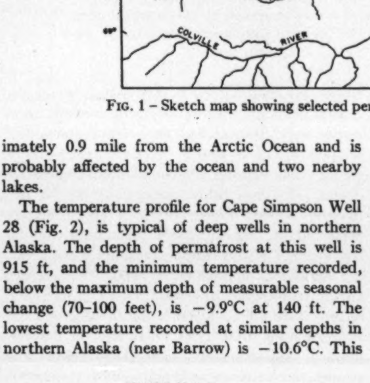

FIG. 2 – Geothermal profile for Cape Simpson Well 28, northern Alaska; data for May 22, 1953, after well had essentially returned to thermal equilibirum

The inverse temperature gradient at Simpson 28 is 74.3 ft/°C from 250 ft through the remaining thickness of permafrost and is essentially the same (74.6 feet/°C) in the 1500 ft of unfrozen sediments immediately underlying the permafrost. These inverse gradients are in the lower portion of the general range (70.4 to 135 ft/°C) of inverse gradients for similar depths in northern and central Alaska.

FACTORS MODIFYING THE TEMPERATURE OF PERMAFROST

Seasonal variations—Measurable (0.01°C) seasonal temperature fluctuations in permafrost extend to at least 70 ft in the Barrow area and may reach 100 ft.

The time-temperature curves for depths of 10, 21, 30, and 60 ft, together with a histogram of air temperatures, by five-day averages, for a typical Barrow station during the period April 1950–July 1952, (Fig. 3), are in general sinusoidal. A degree of asymmetry is noted in all curves but is more prominent at 10 and 21 feet. As the depth of measurement increases, this asymmetry dies out, and at 60 ft it is no longer noticable. The asymmetry is produced by the difference in the manner of heat passage through the active layer during the periods of thaw and freeze-up. (The active layer is ground that lies above the permafrost and thaws in the summer and freezes in the winter.)

In the spring the active layer is completely frozen. When the surface temperature starts to

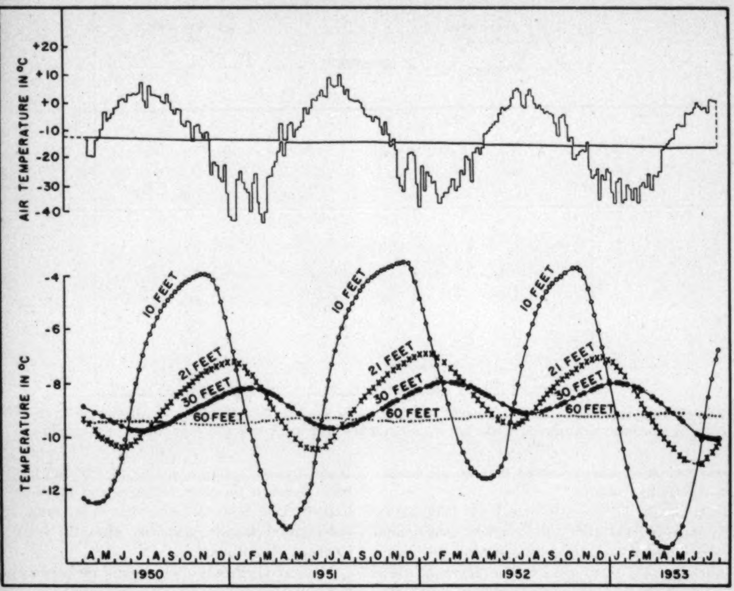

FIG. 3 – Time-temperature curves for various depths in permafrost near Barrow, Alaska, plus the corresponding air temperatures for the same period; the air temperatures are plotted using a five-day average and a datum line of −12.2°C (average annual air temperature at Barrow)

increase, the warm temperature wave gradually begins to penetrate the ground at a rate that depends on the rate of warming of the ground surface and the properties of the surface and subsurface materials. The heat and the resulting warm temperature wave can penetrate the ground for several weeks before surface melting takes place. When surface melting does take place, it does not perceptibly alter the rate of penetration of the warm temperature wave, which may have already reached a depth of 15 ft.

A different phenomenon occurs in the fall. When freezing begins at the surface, a sandwich of unfrozen ground in which the temperature is very near 0°C is caught between the downward freezing surface and the permafrost table from which a small amount of upward freezing may also be taking place, the amount depending mainly on the moisture content of the active layer material. The temperature of the permafrost just below the active layer cannot decrease as long as part of the active layer remains unfrozen (few days in sand to several weeks in wet tundra areas). Thus the cold wave may not begin to penetrate the permafrost for several weeks, the period of zero curtain. (The zero curtain is the interval of time during which the temperature remains constant as the chilling of water is temporarily compensated for by the latent heat of fusion [*Muller*, 1947].) During this period the temperatures in the shallow permafrost either rise slowly or remain constant. Once the active layer is frozen the cold temperature wave can penetrate very rapidly (Fig. 4), because the thermal gradient is very great near the surface.

As the annual temperature wave passes into the ground its amplitude diminishes and its phase is progressively retarded with increasing depth. Thus the annual temperature range in 1951–1952 (Fig. 3), decreased from 8.01°C at ten feet to 0.07°C at 60 ft and the phase of the temperature

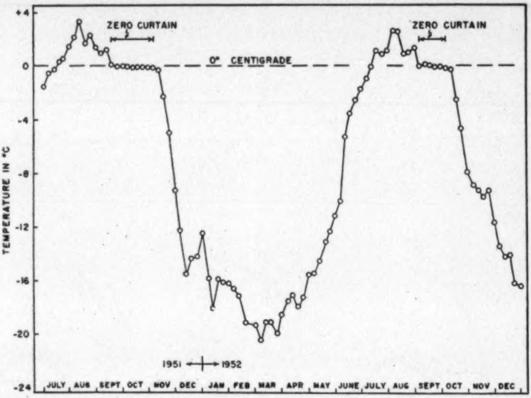

FIG. 4 – Time-temperature curve at a depth of ten inches for a tundra area near Barrow, Alaska; the curve shows a prominent 'zero curtain' in the fall of each year but little if any indication of a spring 'zero curtain'

wave at 30 ft lagged behind that at the surface by about five months.

Although the average annual air temperature at Barrow is −12.2°C, the average annual temperature at the top of permafrost often lies within the range of −7.0 to −9.5°C. The difference, which may reflect differing surface conditions including snow cover, soil-moisture content, or other physical properties, and micrometeorological conditions, is even greater in the Umiat and Fairbanks areas and points up the fact that caution should be used in interpreting permafrost temperatures strictly on the basis of air temperature data.

Heated buildings—When the floor of a heated building rests directly on or is just above (with no air circulation between the floor and the ground) ground containing permafrost, four effects are soon noted. The first and most evident is a melting of the ice wedges and other ground ice for a depth of several feet immediately beneath the building. This melting will usually cause a differential settlement of the floor of the building. The maximum settlement is often near the center of the building although the position of the point of maximum settlement can be displaced toward the location of the furnace or other heating unit. Differential settlement of as much as 20 inches within three or four years has been noted in a building at Barrow. Such differential settlement has often made it necessary to replace the floor within two or three years after heating of the building began. If the heating is stopped at a later date the thawed basin beneath the floor refreezes and the floor is heaved. One foot of heave has been noted in buildings at Barrow one year after the heating has been discontinued.

The second effect is a warming of the permafrost beneath the building. The average annual temperature may be raised by as much as 15 to 20°C just below the floors of buildings at Barrow. The increase in temperature decreases rapidly with depth (to approximately 4°C at 20 feet beneath the center of a 40 x 100-ft quonset hut after five years) but is still measurable at 50 ft. It would not be surprising if it were still measurable (greater than 0.01°C) at depths of more than 100 ft, beneath the center of a building of this size.

The third result is a damping of the amplitude of the temperature fluctuation beneath the building. This damping occurs rapidly and is very effective especially at shallow depths. A comparison of the time-temperature curve at a depth of ten feet beneath a tundra-covered area (Fig. 3) and beneath a building (Fig. 5) indicate that the damping has reduced the amplitude of the seasonal fluctuations from approximately 5°C to a few tenths of one degree C. A time lag in the rate of seasonal penetration of the warm and cold waves is still noted beneath the building.

Edge or side effects on the ground temperatures are also introduced by constructing a heated building on permafrost. These effects are noted

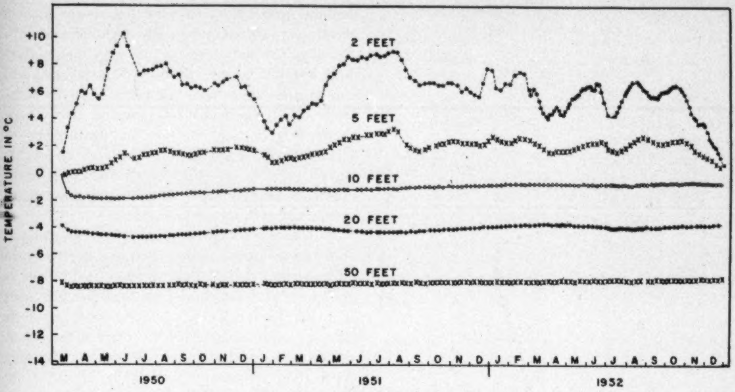

FIG. 5 – Time-temperature curves beneath a 40 × 100-ft quonset hut constructed at Barrow, Alaska, during the summer of 1947; a five-inch reinforced-concrete floor rests directly on gravel mat overlying original tundra surface

particularly in the 20-ft depth time-temperature curve, Figure 5. The side effects are shown in the form of an increased amplitude of temperature fluctuation caused by seasonal temperature changes at the 20-ft depth (also markedly shown at all depths from 16 to 32 ft) over that shown at the 10-foot depth. This fluctuation is consistent with the so-called 'hemisphere rule" which states that the edge effects on temperatures beneath the center of a building should become dominant at a depth approximately equal to one-half of the smaller dimension of the building. This rule is an empirical one based on field observations at Barrow. It has partial justification from theoretical considerations.

The effect of a heated building on the underlying permafrost temperatures shown by a comparison of temperatures in a tundra area and from beneath

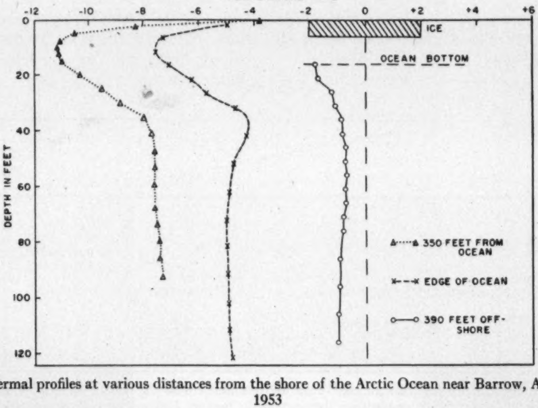

FIG. 6 – Geothermal profiles at various distances from the shore of the Arctic Ocean near Barrow, Alaska, May 21, 1953

TABLE 1 – *Temperatures at 90-ft depths near the Arctic Coast*

Location	Temperature
	°C
390 ft offshore	−0.96
edge of ocean	−4.91
350 ft onshore	−7.33

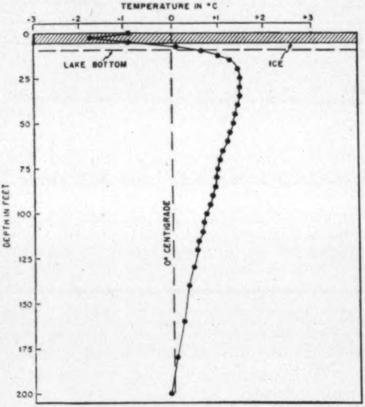

FIG. 7 – Geothermal profile beneath fresh water lake, Barrow, Alaska, May 26, 1953

a building would generally apply to any building constructed directly on permafrost in northern Alaska. The effect would be little altered by either the removal of the original tundra surface or the addition of a few inches of gravel fill. If, however, the building were placed on piles that would allow a natural air circulation beneath the building or if a forced air ventilation system) to be used in winter) were installed between the floor of the building and the ground, the underlying permafrost temperatures would be much less affected than those shown (Fig. 5), and the time-temperature curves might closely resemble those beneath an undisturbed tundra area (Fig. 3). The building would normally be safe from troubles, resulting from permafrost, with these precautions.

Proximity of the Arctic Ocean—The effect of the ocean on permafrost temperatures either becomes all important as the distance from land increases or dies out as the distance from the ocean increases (Fig. 6). The temperatures at a depth of 90 ft for various distances from the edge of the ocean on May 21, 1953 are given in Table 1. At this depth these temperatures should be affected only slightly by seasonal changes. The temperatures beneath the edge of the ocean should approximate the average of the landward and oceanward temperatures at and below 90 feet if we neglect the transient effects of a shifting shoreline and climatic variation and the thermal effect of a nearby lake (oral communication, A. H. Lachenbruch). The three temperatures given in Table 1 seem consistent with this theory.

The depth of permafrost decreases from an indicated depth of 1330 feet eight miles inland to indicated depths of 1045 feet 1200 feet from the ocean, and 670 ft, 400 ft from the ocean [*MacCarthy*, 1952]. The 1045- and 670-ft depths may be slightly modified by nearby lakes. The permafrost temperatures increase rapidly as the ocean is approached and for the first few hundred feet out under the ocean. In spite of this rapid

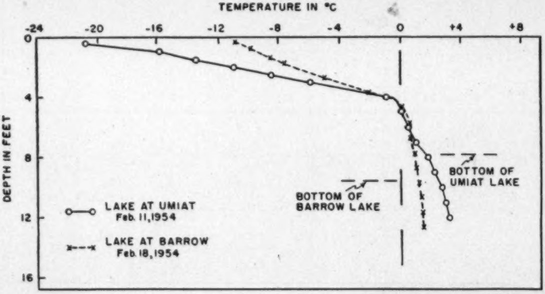

FIG. 8 – Winter thermal profiles through lakes near Barrow and Umiat (2/11/54), Alaska (Umiat data part of a cooperative project with Boston University)

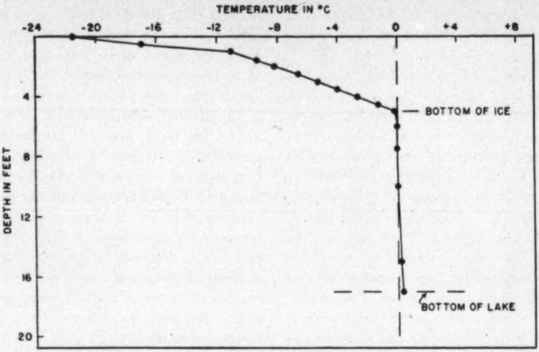

FIG. 9 – A winter thermal profile through the Colville River near Umiat, Alaska, February 19, 1954 (project conducted in part by Boston University)

increase in temperature, data from the ocean station suggest that the thickness of permafrost is still more than 400 ft at a distance of 390 ft from shore. Oceanographic investigations have shown that bottom ocean waters having a temperature below 0°C are expected until depths on the order of 500 to 1000 ft are reached. Permafrost must therefore extend seaward to ocean depths of 500 to 1000 ft.

If the formations beneath the ocean site 390 ft from shore contain fresh water, it appears from the graph that they would be frozen. If the formations contain sea water, they are definitely not frozen. Because a concentrated brine is found at depths of from 10 to 160 ft on land near shore and because sea water overlies these formations, it has been tentatively concluded that frozen ground does not exist beneath the ocean floor for more than a few hundred feet offshore. The driller's log for the hole indicated no frozen material to 100 ft, the possibility of frozen ground from 100 to 205 ft, and the possible existence of unfrozen layers (referred to as taliks in Russian) from 205 to 326 ft. By definition, however, the formations throughout all but the top few feet penetrated by the hole are in permafrost.

Shallow lakes and rivers—Much of the land surface of the Alaskan Arctic coastal plain is covered by shallow lakes. The lake basins in the Barrow area, seem to fall into two general depth ranges, either two to three feet or six to nine feet. In lakes two to three feet deep the thaw will penetrate to the bottom of the lake and commonly into the sediments from a few inches to possibly two feet during the summer. This active layer becomes frozen by midwinter. The permafrost temperatures at depth under these lakes are higher than those under the surrounding tundra, usually on the order of 0° to 3°C depending on the size and depth of the lake.

Lakes six to nine feet deep do not freeze to the bottom. The depth of the unfrozen basin beneath varies according to the size of the lake, depth and size of the six- to nine-foot part, and the long-term

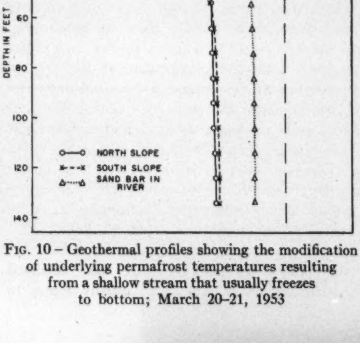

FIG. 10 – Geothermal profiles showing the modification of underlying permafrost temperatures resulting from a shallow stream that usually freezes to bottom; March 20–21, 1953

average annual temperature of the water. The geothermal profile beneath a fresh water lake six to nine feet deep and approximately 2500 ft in diameter is shown in Figure 7. This profile was taken in late winter when the ice was thickest, about six feet, and the water was only three feet deep. The temperature of the water ranged from 0.5 to 1.0°C. The depth to permafrost under this part of the lake is 190 ft, although the permafrost may actually be unfrozen to greater depths because of the possibility of a high brine content in the formations. The temperature profile beneath this lake (Fig. 7) would continue to show decreasing temperatures to some depth where a minimum would be reached. Below this depth, the temperature profile would be expected to show a thermal gradient approaching that common to the surrounding area at similar depths.

A comparison (Fig. 8) of the thermal regimes of a lake at Barrow on the coastal plain and a lake at Umiat in the foothills indicates that both lakes have unfrozen basins beneath them. However, the temperatures of the bottom sediments in the Umiat lake are approximately 2°C higher than those at Barrow. The difference is approximately the same as that noted in permafrost temperatures in the two areas. The differences in permafrost temperatures can be traced to the differences in average annual near-surface ground temperatures. The longer ice-free period at Umiat also contributes to the higher lake-bottom temperatures in that area. The differences in the lake-bottom temperatures at Barrow and Umiat as well as the differences in permafrost temperatures between the two places illustrates the risk involved in the indiscriminate use of average annual air temperatures to predict ground temperatures because Barrow and Umiat have almost identical average annual air temperatures.

A thermal profile through the ice and water to the bottom of the Colville River at Umiat (Fig. 9) is nearly vertical beneath the ice and differs markedly from the lake profiles at Barrow and Umiat (Fig. 8). One explanation for this difference is that the lakes are relatively stagnant in winter and a more moderate thermal gradient develops. The mixing caused by turbulence in the river water prevents the development of a similar gradient beneath the river ice. This turbulence also accounts for the heavy concentration of ice crystals in the water (to a depth of 12 ft in 1953) beneath the river ice in early fall.

Permafrost temperatures are also modified beneath shallow streams that usually freeze to bottom (Fig. 10). One hole was drilled on a small sand bar in the middle of the west fork of the Shaviovik River. Holes were also drilled a quarter of a mile on either side of the hole on the sand bar in the river. The data from all three holes were obtained soon after they were drilled, using air as the fluid, and the temperatures had not completely returned to equilibrium. However, they indicate that the river has introduced approximately 3°C of warming into the permafrost to a depth of 135 ft. Barring any other permafrost temperature modifications these profiles would be expected to converge at greater depths.

From these results and other data, it seems reasonable to make the following general remarks about lakes and rivers in northern Alaska: (1) In this region of the Arctic, lakes having a diameter of approximately one-half mile or more and a depth of at least seven feet may be expected to have unfrozen basins beneath them to a depth of 200 ft or more. (2) Should these lakes be underlain by sands or gravels of favorable water-bearing characteristics they could provide a limited and probably not immediately replenishable winter water supply. (3) Should these lakes lie within five miles of the Arctic Coast the underlying formations may contain saline rather than fresh water. (4) The best year-around fresh-water source in the Arctic is an uncontaminated lake or stream, provided that the minimum depth at some part of the body of water is at least seven or eight feet.

Acknowledgments—The work in northern Alaska has been done by the U. S. Geological Survey with the cooperation and support of the Office of Naval Research and its Arctic Research Laboratory at Barrow, Alaska, the Bureau of Yards and Docks, of the U. S. Navy, and the Snow, Ice and Permafrost Research Establishment of the Corps of Engineers, U. S. Army.

Acknowledgment is also extended to the Boston University Keys Project personnel for assistance in obtaining data presented in Figures 8 and 9.

A Method for the Measurement of Absolute Gravity

RICHARD A. HAUBRICH, JOHN C. ROSE, AND G. P. WOOLLARD

Abstract—The greatest difficulty in measurements of absolute gravity with either pendulums or falling bodies is the distance determination. It is proposed to avoid the distance measurement in a falling-body experiment by determining g in terms of c, the velocity of light. A pulse of light is directed up toward and reflected from a falling ball. The reflected light pulse, upon being detected by a photomultiplier, initiates a new pulse. A pulse recycle oscillator is thus set up whose frequency is a function of the position of the ball. By measuring the frequency for three successive time intervals, g may be determined in units of c independent of the time and position at the release of the ball.

Introduction—The precise determination of the acceleration of gravity has long been a problem of scientific importance, and despite many painstaking experiments involving years of work there is still an apparent uncertainty of about five milligals (0.005 cm/sec^2) in the best measurements and about 12 mgal in the international datum value adopted for relative gravity measurements. Since the gravitational unit is fundamental to many other measurements, and the above inaccuracies constitute a limiting factor in many experiments, there is a definite need for a method that will permit the reliable determination of g to 1 mgal or better. As *Silsbee* [1956] has stated, knowledge of the absolute value of g is an essential link in at least two fundamental measurements of physics. The unit of electric current, the ampere, is defined in terms of the force developed between two current-carrying conductors in a specified geometrical configuration. By far the most convenient method for measuring this force is to balance it against the weight, mg, of a known mass m. It is from the ampere thus determined that other units, such as the watt, joule, oersted, and gauss, are derived. The other measurement is to use g in determining the force on a conductor while it is carrying a known current in a magnetic field. This, when combined with the measured resonance frequency of protons when in that field, yields the gyromagnetic ratio of the proton, one of the very fundamental atomic constants.

With the advent of the International Geophysical Year and the international gravity and satellite programs, the need for a more precise determination of g is brought into prominence on several problems. Some of these are the adoption of a standard international gravitational unit, the coordination and integration of the world's gravity data, the determination of the undulations of the geoid, the geoidal positions of the continents, and the shape of the Earth. From the orbital configuration and motions of the IGY satellites it should be possible also to determine independently, to a higher degree of accuracy than hitherto, the degree of polar flattening of the Earth and the product of the mass of the Earth with the gravitational constant. These measurements, coupled with a more precise value of g would permit a revision of several fundamental geophysical constants.

Methods of investigation that have been used for determining g—To determine absolute gravity there are two fundamental methods, one based on the period of a freely oscillating pendulum and the other on changes in velocity of a freely falling body.

Pendulum methods can be recorded very easily, but require precise measurement of both length and time as well as a flexure correction for the pendulum to one part in a million to obtain an accuracy of one milligal. An associated problem is the change in length of the pendulum when suspended on its knife edges. For a one meter pendulum, the length increase for suspension by its upper end is about one part in a million, which must be measured and corrected. This is difficult. If the pendulum is made longer, it becomes easier to measure the elongation, but the increase in mass exerts more force on the support and the pendulum is subject to greater flexure. The amount of flexure is very difficult to measure and the effects hard to evaluate. The most precise pendulum observations yet made, those at the Potsdam Geodetic Institute in Germany (Revised Potsdam value, by Harold Jeffreys based on different flexure corrections from those originally used, which gave a disagreement of over 12 mgals with other sites), the National Physical Laboratory at Teddington, England, and the National Bureau of Standards in Washington, D. C. have a standard deviation of six milligals for absolute g when intercompared on a relative gravity basis. While pendulums are again being used for the present measurements in Buenos Aires, Argentina, there appears to be fairly general agreement that the pendulum method can not determine absolute g with a reliability of one milligal and probably no more than three to four mgals.

The other classical mechanics scheme used to determine absolute g is to measure the velocity changes of a freely falling body. Most of the free-fall methods have employed some sort of rod for the falling body. While the rod can be accurately scribed with distance marks, there are longitudinal rod oscillations resulting from release of the rod which are difficult to measure. As the enclosing tube probably oscillates as a consequence of releasing the rod, this means that the rod and recording device could oscillate out of phase with each other. Because the amplitude of this oscillation is on the order of 10^{-6} of the length of the rod, there is a resulting uncertainty of one or two milligals that is inherent in the method assuming that recording presents no significant problem, which it does. The observations have been difficult, expensive, and not altogether satisfactory, as evidenced by the experience of Volet in France over the past ten years and that of the National Research Council group in Canada over the past seven years.

In summary, the methods tried to date all have been severely handicapped by mechanical difficulties, in part related to the measurement of length and flexure and in part related to the one-shot spot-sampling methods of recording. These limitations have resulted in errors that are extremely difficult to evaluate and led to uncertainties in the determination of g of the order of several milligals.

In order to get a more accurate determination of g, it is felt that an entirely different experiment and procedure is required; one that will circumvent the difficulties attendant upon the methods described. It is believed that this can be achieved by dropping a ball rather than a rod and by using the velocity of light as a standard of measurement for determining the change in rate of fall. While the idea of dropping a ball rather than a rod is not new, the idea of using the velocity of light as a means of determining the change in rate of fall is believed to be new and the significant departure from the previous techniques tried. (E. C. Bullard in personal conversation with G. P. Woollard proposed a few years ago a measurement of g whereby a ball would be flipped by a spring vertically upward and its change in velocity noted both on the rise and fall from the point of maximum rise.)

General considerations and proposed method—According to *Eddington* [1949] the standard of of length must be a quantum specified structure. Eddington shows that the unique quantum specified metric is the same as the σ metric where σ is the local uncertainty of position in a given direction, that is, the standard deviation of the mean value of a wave packet. It is then possible to show that the use of the wave length of the H_α line is equivalent to using the σ metric. Therefore, the unit of length may be taken as the wave length of the H_α line (or some other quantum specified wave length). The standard of time is likewise defined by the period of light waves. The ratio of the wave length to the period of H_α light is the velocity of light, and this quantity must be constant for all places and times. Since the velocity of light is a ratio of the fundamental units of length and time, it follows that it is a fundamental unit of velocity.

It should, therefore, be possible to measure g in terms of the standard velocity c, the velocity of light. The expression for g is then in terms of c divided by time and there is no need to express or to measure lengths in any other units. The final expression for g will be in terms of units just as fundamental as any others that might be used. The units will be more fundamental and more truly standard than those usually expressed, namely, units based on the standard meter.

The velocity of light is known now to an accuracy of about one part in a million, and the system of equations which follow give g in terms of c. With a better value for the velocity of light, and a timing accuracy of 10^{-8} sec, g could be obtained to 0.1 mgal with the method proposed. It also should be possible to measure the velocity of light in the evacuated tube by setting up a half-silvered mirror system where the distance between mirrors could be measured with an interferometer.

It is also worth mentioning that balls of different masses can be dropped, permitting a test of the fundamental Einstein postulate of the equivalence of inertial and gravitational mass to a six-place accuracy.

Because of the small and symmetric nature of a dropped ball, and because it is expendable, many other variations of the proposed experiment are possible. Some of these are: (1) dropping electrically charged or magnetized balls (of course external fields could be shielded as desired), and (2) application of external electric and/or magnetic fields.

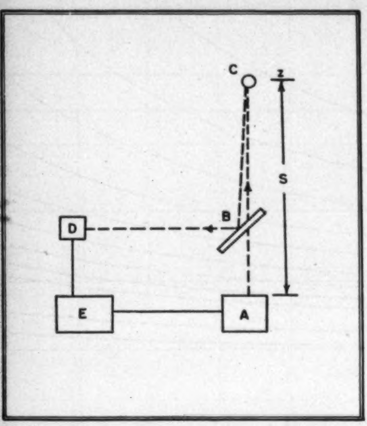

FIG. 1 – Schematic drawing of proposed experiment; A, light pulser; B, half-silvered mirror; C, falling ball; D, photomultiplier; E, pulse forming circuit

Proposed experiment—The following experiment is proposed. A spherical body is dropped from a position taken as the origin of the coordinate axes and falls in the positive z-direction starting from rest at time $t = 0$. At a time t

$$z = \tfrac{1}{2}gt^2 \tag{1}$$

where $z = 0$ at time $t = 0$.

The distance measurement is eliminated by using pulses of light to determine the instantaneous position of the body. The procedure would be to send a pulse of light up to the freely falling spherical body. The light pulse is reflected from the bottom surface of the body to a light sensitive device adjacent to the light pulser. When the reflected light pulse is detected it initiates a new pulse from the source. The light source may be modulated electronically by some means, as the Kerr effect. The pulses may be detected by a suitable light detecting device, such as a photomultiplier tube, as shown schematically in Figure 1.

Theoretical development—Let S be the distance from the source to the ball at time t and also the distance from the ball to the photocathode of the photomultiplier. Let S_0 be the distance from the Kerr cell or photomultiplier to the plane $z = 0$ (the release point). At some time t after the ball is released a pulse of light is sent out from the Kerr cell, travels distance S to the ball and then reflects back distance S to the photomultiplier. The resulting output pulse of the multiplier is fed through a pulse-forming circuit generating a new pulse from the Kerr cell. As each succeeding pulse is received by the multiplier, it generates the next light source pulse.

Let τ_1 = time delay in the photomultiplier tube
τ_2 = time delay in intervening pulsing circuits
τ_3 = time delay in the Kerr cell

Since τ_1, τ_2, τ_3 are constants, let

$$T_0 = \tau_1 + \tau_2 + \tau_3 \tag{2}$$

At any instantaneous time t the time of travel of the light pulse from the light source to the ball and back to the photocathode will be

$$\Delta t = 2S/c \tag{3}$$

where c = velocity of light; the instantaneous frequency ν for one complete cycle will be

$$\nu = 1/(\Delta t + T_0) = c/(2S + cT_0) \tag{4}$$

Since

$$S = S_0 - z \tag{5}$$

it follows from (1)

$$\nu = c/[(2S_0 + cT_0) - gt^2] \tag{6}$$

Letting

$$K = 2S_0 + cT_0 \tag{7}$$

(6 becomes)

$$\nu = c/g(K/g - t^2) \tag{8}$$

Integration between times t_1 and t_2 for $t_2 > t_1 > 0$ gives

$$N_1 = \int_{t_1}^{t_2} \nu\, dt = \frac{c}{g}\int_{t_1}^{t_2} \frac{1}{(K/g - t^2)}\, dt$$

$$= \frac{cg^{-\frac{1}{2}}}{2\sqrt{K}} \ln \frac{\sqrt{K/g} + t}{\sqrt{K/g} - t}\bigg|_{t_1}^{t_2} \tag{9}$$

or

$$N_1 = \frac{cg^{-\frac{1}{2}}}{2\sqrt{K}} \ln \frac{(\sqrt{K/g} + t_2)(\sqrt{K/g} - t_1)}{(\sqrt{K/g} - t_2)(\sqrt{K/g} + t_1)} \tag{10a}$$

where N_1 is the number of cycles or events in the time interval $t_2 - t_1$. Similarly for time intervals $t_3 - t_2$ and $t_4 - t_3$ we obtain the result

$$N_2 = \frac{cg^{-\frac{1}{2}}}{2\sqrt{K}} \ln \frac{(\sqrt{K/g} + t_3)(\sqrt{K/g} - t_2)}{(\sqrt{K/g} - t_3)(\sqrt{K/g} + t_2)} \tag{10b}$$

$$N_3 = \frac{cg^{-\frac{1}{2}}}{2\sqrt{K}} \ln \frac{(\sqrt{K/g} + t_4)(\sqrt{K/g} - t_3)}{(\sqrt{K/g} - t_4)(\sqrt{K/g} + t_3)} \tag{10c}$$

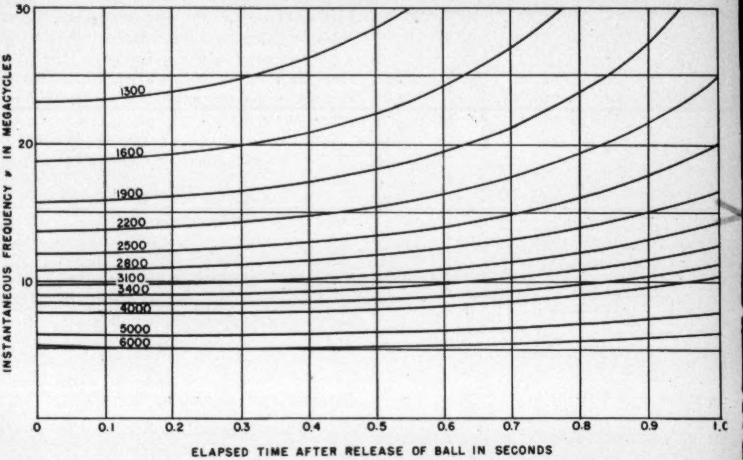

FIG. 2 – Instantaneous frequency versus elapsed time after release of ball for values of K from 1300 to 6000; $\nu = c/(K - gt^2)$

This gives a set of three equations with three unknowns g, K, and t_1. Since the equations are non-linear, it is necessary to use numerical approximation methods for their solutions. Among the methods which can be used, the Newton-Raphson method seems to work well and can easily be applied. Solution is adaptable to the use of an electronic digital computer, such as the IBM model 650.

Sensitivity considerations of falling-ball experiment—The pulse recycle frequency for light pulses reflected from a falling ball is

$$\nu = c/(K - gt^2) \tag{11}$$

where $K = 2S_0 + cT_0$
t = time after start of ball drop in seconds
S_0 = distance in cm from the light-source detector to the ball at time $t = 0$
T_0 = delay time in electronic circuits in sec
c = velocity of light in cm/sec
g = value of gravitational acceleration in gals

Figure 2 shows plots of the family of frequency curves for different values of K. Figure 3 gives the possible values of S_0 and T_0 for each K plotted in Figure 2.

The experimental procedure would be to count the number of recycle pulses in a time interval $(t_2 - t_1)$ where $t_2 > t_1 > 0$. To measure g independent of the initial conditions, it is required to measure the number of counts over three different time intervals. The number of counts in $(t_2 - t_1)$ is

$$N = \int_{t_1}^{t_2} \nu \, dt \tag{12}$$

The sensitivity is the change in number of counts per change in g or

$$dN/dg = (d/dg) \int_{t_1}^{t_2} \nu \, dt = \int_{t_1}^{t_2} (d\nu/dg) \, dt \tag{13}$$

where differentiation under the integral sign is permitted since the integration is independent of g.

Now $d\nu/dg = ct^2/(K - gt^2)^2$

$$\therefore dN/dg = \int_{t_1}^{t_2} [ct^2/(K - gt^2)^2] \, dt \tag{13a}$$

Upon integrating by parts

$$dN/dg = ct/2g(K - gt^2) \Big|_{t_1}^{t_2} - \int_{t_1}^{t_2} c \, dt/2g(K - gt^2) \tag{13b}$$

Substituting in the value of ν given in (11)

$$dN/dg = (1/2g)[t_2\nu_2 - t_1\nu_1 - N] \tag{14}$$

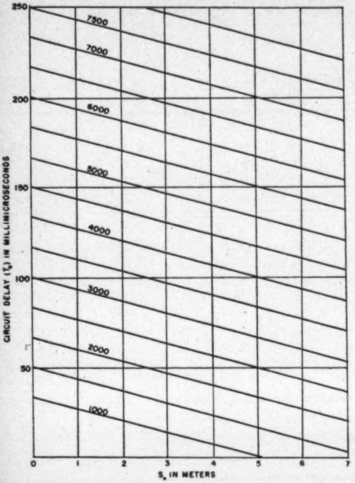

FIG. 3 – Circuit delay time T_0 versus drop height S_0 for values of K from 1000 to 8000; $K = 2S_0 + cT_0$

where ν_2 and ν_2 are the frequencies at times t_1 and t_2 respectively. From the plot of the relationship of ν to t (Fig. 4) it is possible to express Equation (14) in a more convenient form. Comparing (14) with Figure 4, it is seen that

$$2g\, dN/dg = \text{shaded area}$$

since $\nu_2 t_2$ and $\nu_1 t_1$ represent rectangular areas and N represents the area under the curve between t_2 and t_1, by (2).

$$\text{The shaded area} = \int_{\nu_1}^{\nu_2} t\, d\nu = \int_{t_1}^{t_2} t(d\nu/dt)\, dt$$

For small values of $t_2 - t_1 = \Delta t$

$$dN/dg = (1/2g)\ (t(d\nu/dt)\Delta t)$$

From (11) $d\nu/dt = 2cgt/(K - gt^2)^2$

$$\therefore dN/dg = [ct^3/(K - gt^2)^2]\Delta t \qquad (15)$$

This expression gives the sensitivity in counts per gal in terms of t, K, and Δt when the latter are given in cgs units. Table 1 gives values of the sensitivity in counts per milligal for different experimental parameters as calculated from (15). The sensitivities are given for the first of three equal intervals of time of $\Delta t = 0.1$ sec.

This is thus the minimum sensitivity because the latter two intervals having larger values of t will have higher values of dN/dg. The value of t was chosen at the center of each 0.1 sec time interval and the resultant error in dN/dg due to the finite value of Δt is not more than a few per cent; this is quite sufficient to allow a choice of parameters to get an adequate sensitivity. S_0 is the distance from the drop point to 50 cm beyond the last of the three counting intervals. The 50 cm at the bottom allows time and space to deflect the ball at the end of its fall. R is the height at which counting actually begins. Even in cases where a long tube is needed to drop the ball, the light-reflection problem is not great as the recording of data is only done during the last part of the fall. Little sensitivity is gained by recording the initial part of the fall, that is, when t is small. There are two advantages in recording over a shorter time toward the end of the fall: (1) a shorter light path to the ball during recording, and (2) a narrower band width of frequencies. It also should be mentioned that if the ball is given an initial velocity, the tube length need only be a little longer than R_1, thus improving portability.

In Table 1 the sensitivity calculated for each corresponding pulse recycle frequency range is given along with the requirements of tube height, delay time and counting accuracy to obtain results accurate to 1 mgal. It is felt that the delay times of Table 1 are quite realistic. $T_0 = 10^{-7}$ sec should be easily attainable and 5×10^{-8} can probably be reached with a little refinement. A photomultiplier tube like the RCA 6810 has a delay of from 2 to 3 $\times\ 10^{-8}$ sec. The transit time through the light source will be 1 or 2×10^{-8} sec. Pulse shapers and amplifiers will account for the remainder of T_0. A typical pulse amplifier as the Hewlett Packard

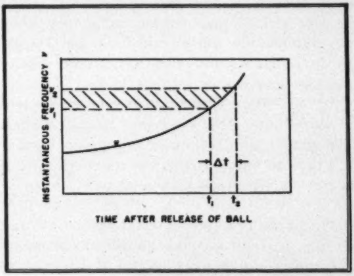

FIG. 4 – Instantaneous frequency (ν) as a function of time after release of the ball

TABLE 1 – *Minimum sensitivity at different dropping heights for three different delay times*

Pulses are counted during 0.3 sec of fall. The ball is 50 cm from the bottom of the tube at the end of counting.

[a] R is the height at which counting began.

[b] Sensitivity is for the first 0.1 sec interval of 3 intervals counted.

460AR has a delay of 1.4×10^{-8} sec. A delay of 8×10^{-8} is thus possible with presently available components. New types of photomultiplier tubes such as the transmission type multiplier now in development at Westinghouse promise to give a shorter transit time than the RCA 6810.

The proposed method of counting pulses is to display pulses as modulation dots on an oscilloscope trace. The traces will be modulated to give a raster of traces as on a television screen. A TV monitor will resolve as many as 500 lines, both vertically and horizontally. This will allow as many as a fourth of a million dots on one tube face. The total number of pulses in a run would be from 3–6 million. But it is not necessary to display every pulse on the screen. Suppose the intensity of the dots is varied so that every tenth dot is brighter, every hundredth is brighter still, etc. This could be done with a beam switching tube which when run continuously will operate to 20 mc. The intensity coding will thus allow a good proportion of the dots to be left out.

An oscilloscope with a fast sweep could be used to spread dots to one centimeter apart or greater. Timing marks in the form of fast rise time pulses will then be introduced on the traces from a frequency standard such as those made by Hycon or Knights, which are stable to one part in 10^{-9}. With fast rise times on both pulse recycle dots and on time marks, it should be possible to determine the number of pulses per interval of time to $\frac{1}{10}$ of a pulse or better at frequencies below 20 mc. The scope traces can be photographed using standard oscilloscope trace photographing techniques. This has the advantage of producing a clear and permanent record of results.

Size of apparatus—From Table 1 a typical example of instrument parameters would be $S_0 = 655$ cm or about a 22 ft tube. The maximum height of the ball during recording would be 335 cm or about 11 ft. At $T_0 = 8 \times 10^{-8}$ sec the minimum sensitivity is about $\frac{1}{4}$ count so that a determination of $\frac{1}{10}$ count would allow a g determination of ±0.5 mgal. The frequencies would be from 9.7–12 mc.

It is therefore apparent that with a reasonable size drop tube and light path with a delay time in the electronics of 8×10^{-8} seconds, a result accurate to at least one milligal is possible.

Static stability evaluations—Starting with the expression for the frequency

$$\nu = c/(K - gt^2) = ct^2/(K/t^2 - g)$$

$$K = 2S_0 + cT_0$$

it is seen that a change in g of one milligal will be equivalent to a change in K/t^2 of 10^{-3} gals. Consider the case where $S_0 = 655$ cm, $t = 0.85$ sec, and $T_0 = 8 \times 10^{-8}$ sec which gives sufficient sensitivity. Then

$$K/t^2 = 10^{-3} \text{ gals}$$

$$K = 0.722 \times 10^{-3} \text{ cm}$$

$$S_0 = 0.361 \times 10^{-3} \text{ cm}$$

Thus a change of 3.61×10^{-4} cm between the ball and the source will produce an error of one milligal. Note this is calculated at $t = 0.85$ sec or at the same instant for which the sensitivity of 0.24 counts/mgal was calculated in Table 1. The change in distance can occur either at the ball or at the source detection end. The changes in ball size during the 0.3 sec of recording will be negligible. For steel the temperature coefficient of expansion is 10^{-5} per degree C. The change in shape of a one-centimeter radius steel ball due to deformation caused by the force of its own mass would be about 10^{-8} cm. The base upon which the recording unit sits would have to remain stable to 3.61×10^{-4} cm for 0.3 sec. It does not appear that temperature changes over this short a time will be significant. Vibrations caused by seismic activity or other sources might well cause some error. However, these may be monitored and drops made when conditions are quiet. It might be mentioned that in the Michelson-Morley experiment static stability of 6×10^{-7} cm had to be maintained.

As the ball drops, the radius of the spherical wave front at the photomultiplier face decreases. This will produce an error due to a change in rise time of the signal input. Using the values 50 cm and 355 cm as the limits of the ball's distance during recording, the difference in curvature of the wave front will produce a rise time error equivalent to a displacement of 3.4×10^{-3} cm. This is equivalent to about 100 mgals. Though optical methods of compensation could be used, it is felt that it would be simpler to correct for the error. Static tests could easily evaluate the effect to better than one per cent, which would be sufficient to get one-milligal accuracy. It should be added that other effects dependent upon the distance of the ball from the source such as variation in light intensity might be corrected for by running static tests and actually calibrating to determine the error introduced.

Portability of the equipment—The sensitivity of the experiment increases as the velocity of the ball increases. The obvious way of getting high initial velocity during the recording time interval is to drop the ball through a greater path length. With increased sensitivity a smaller recording time interval may be used. The result is that regardless of the total path length, the recording is done only during the time the ball is within two or three meters of the pulsing and pick-up devices. This suggests that the drop tube need not be any more than three meters in length provided that some small precise spring device at the top "shoots" the ball downard. In fact, portability of the tube is no great problem even if it were long since it could be made in sections that fit together with O-ring vacuum seals. The pulser and pick-up devices do not need to be in the vacuum, that is, the bottom of the tube can be terminated with a piece of plate glass. The intervening air space between glass and transducer would act as a short time delay filter, easily constant during the 0.3 sec duration of the recording.

Preliminary experimental tests—The first phase of the experiment now in progress is to set up a recycle light oscillator and test for frequency stability. The requirements for this are a light source capable of 10 – 20-mc modulation, a high sensitivity, fast photomultiplier, and the intermediate pulse shaping and amplifying circuitry. In this initial stage of the experiment static tests of frequency stability are being made by choosing a light path distance such that the pulse recycle frequency is close to the carrier frequency of WWV. The stability of the pulse recycle frequency is governed by the stability of the electron transit times in the electronic circuitry. Since the electron transit time in a vacuum tube varies as the square root of the applied potential, a gravity result accurate to one milligal will require a voltage stability of one part in one million.

Conclusions—The proposed falling-ball method is essentially a continuum experiment, with the advantages that no direct distance measurement is involved, and that mechanical oscillations of the falling ball (if any) caused by release, would be readily observable as cyclic low frequency variations superimposed on the high recycle frequency. The high recycle frequency changes smoothly and uniformly with time. The chief advantage of the method is that for the first time absolute g would be given in terms of a fundamental and universal quantity, the velocity of light. A relatively simple conversion of the gravity method will also permit a precise direct measurement of the velocity of light in a vacuum.

Disadvantages of the falling-ball method are believed to be entirely electronic rather than mechanical. Problems related to geometrical optics such as change in curvature of the wave front arriving at the photomultiplier can be evaluated by static measurements, and corrected. Variable electronic delay time can be partially controlled by use of precise potentials on all vacuum tube devices. Static tests are easy to perform, and the transit time must be stable for only 0.3 sec.

All of the current methods are decidedly not portable and are subject to mechanical as well as electronic problems. The proposed method is felt to have a distinct recommendation in that it can be made portable and *g* can be measured in terms of a universal constant. The problems are principally electronic in nature and can either be circumvented or corrected for. In principle the experiment is capable of yielding 0.1 milligal accuracy. In addition, the method is easily adaptable to tests related to the fundamental nature of gravitation.

Least Squares in Magnetic and Gravity Interpretation

DONALD H. HALL

Abstract—Methods of applying least squares to profiles of magnetic intensity over polarized bodies to obtain the parameters of the anomaly equations are developed, and examples of calculations are given. It is shown that the method is also directly applicable to gravity.

Introduction—In exploration geophysics, as in all the exact sciences, fitting equations of various kinds to observed values is one of the essential operations in treating the data. Magnetic interpretation is no exception, especially in its final stage, when the anomaly field is explained in terms of geological structure. Equations giving the theoretical effects of various bodies, taken to represent geological conditions, are fitted to the observed effects in an attempt to discover the body giving the best representation, and so evaluate parameters giving its position, size, and magnetic properties.

In its simplest form, when profiles are taken across the bodies, interpretation involves fitting to two-dimensional curves. It is this particular form of the problem to which we will confine ourselves here.

One method of solution involves locating critical, inflection, half-maximum and other points, and calculating the parameters from these [*Nettleton*, 1940, p. 224; *Heiland*, 1946, pp. 381–389; *Smellie*, 1956]. The theoretical curve is then plotted and compared to the observed one, and, as is usually necessary, the parameters are readjusted and the curves replotted until a better fit is obtained.

However, any method requiring the judgment of the interpreter at intermediate stages of the calculation has many disadvantages. Especially when calculations can be programmed for the electronic computer, it is desirable to have other methods available, whereby a fit can be systematically determined.

Least squares is such a method. The chief difficulty in its application is that an algebraic solution for the parameters cannot usually be obtained if the equations are not linear. This is usually the case for the equations of magnetic interpretation.

It is the purpose of this paper to examine these equations, with the view of utilizing certain of their properties in obtaining numerical or other indirect solutions for the parameters.

The form of the magnetic equations—The magnetic potential U_p at a point P, due to a body with uniform intensity of magnetization I along the axis s is given [*Jeans*, 1948, p. 375] by

$$U_p = I \frac{\partial}{\partial s} \iiint \frac{dV}{r} \tag{1}$$

where dV is an elementary volume, r is the distance from the element to the observer, and integration is over the body.

The observed quantity is usually magnetic intensity; that is, the derivative of U_p in some chosen direction. Let V represent this quantity. Considering (1), it is apparent that if axes are chosen with the z-axis vertically downward, and if the observer traverses the x-axis

$$V = k\, F(x, d_j) \tag{2}$$

where $k = cI$, c and the d_j being a number of parameters giving the size and position of the body, as well as the direction of magnetization and the direction of measurement.

Let us now examine the application of the theory of least squares in obtaining a best fit of (2) to a number of observed values of V.

Applying least squares to the magnetic equations—By the theory of least squares [*Reddick* and *Miller*, 1938, pp. 345–349], the best fit of a function $y(x)$ to a number of observed values $y_1, y_2, \cdots$ is attained when $S = \sum_i [y_i - y(x_i)]^2$ is a minimum; that is, when the derivatives of S with respect to all the parameters of $y(x)$ are simultaneously zero. Applying this theory to (2), we have

$$S = \sum_i [Vi - kF(x_i, dj)]^2 \tag{3}$$

V_i being the observed values of V at the points x_i, and the conditions for minimal S are

$$\frac{\partial S}{\partial I} = \sum_i 2cF(x_i, d_j)[V_i - kF(x_i, d_j)] = 0 \tag{4}$$

$$\frac{\partial S}{\partial c} = \sum_i 2IF(x_i, d_j)[V_i - kF(x_i, d_j)] = 0 \tag{5}$$

$$\frac{\partial S}{\partial d_l} = \sum_i 2k[V_i - kF(x_i, d_j)] \frac{\partial F(x_i, d_j)}{\partial d_l} = 0 \tag{6}$$

d_l being representative of the d_j. These reduce to

$$\sum_i V_i F(x_i, d_j) - k \sum F^2(x_i, d_j) = 0 \qquad (7)$$

$$\sum_i V_i \frac{\partial F(x_i, d_j)}{\partial d_l} - k \sum_i F(x_i, d_j) \frac{\partial F(x_i, d_j)}{\partial d_l} = 0 \qquad (8)$$

Methods of solving (7) *and* (8)—When $F(x_i, d_j)$ can be expressed in terms of functions of x_i: if

$$F(x_i, d_j) = G_1(d_j) H_1(x_i) + G_2(d_j) H_2(x_i) + \cdots \qquad (9)$$

then, substituting into (7) and rearranging

$$\begin{aligned} G_1(d_j) \Big[\sum_i V_i H_1(x_i) &- kG_1(d_j) \sum_i H_1^2(x_i) \\ &- kG_2(d_j) \sum_i H_1(x_i) H_2(x_i) - \cdots \Big] \\ + G_2(d_j) \Big[\sum_i V_i H_2(x_i) &- kG_i(d_j) \sum_i H_1(x_i) H_2(x_i) \\ &- kG_2(d_j) \sum_i H_2^2(x_i) - \cdots \Big] \\ &+ \cdots = 0 \end{aligned} \qquad (10)$$

Substitution into (8) produces identical equations, hence (10) is a condition for best fit. From (10) we see that

$$\left. \begin{aligned} \sum_i V_i H_1(x_i) &= kG_1(d_j) \sum_i H_1^2(x_i) \\ &\quad + kG_2(d_j) \sum_i H_1(x_i) H_2(x_i) + \cdots \\ \sum_i V_i H_2(x_i) &= kG_1(d_j) \sum_i H_1(x_i) H_2(x_i) \\ &\quad + kG_2(d_j) \sum_i H_2^2(x_i) + \cdots \\ \text{etc.} & \end{aligned} \right\} \qquad (11)$$

These simultaneous equations give values of $G_1(d_j)$, $G_2(d_j)$, $\cdots G_n(d_j)$, from which n parameters can be obtained.

Solution by numerical methods—Assume that $F(x, d_j)$ contains only one parameter, say z.

By solving (7) and (8) simultaneously, we obtain a condition for best fit

$$\frac{\sum_i V_i F(x_i, z)}{\sum_i F^2(x_i, z_i)} = \frac{\sum_i V_i \dfrac{\partial F(x_i, z)}{\partial z}}{\sum_i F(x_i, z) \dfrac{\partial F(x_i, z)}{\partial z}} \qquad (12)$$

By substituting a sequence of trial values of z, its best-fit value Z can be obtained.

A solution can also be obtained by consideration of

$$\sum_i V_i F(x_i, z) \Big/ \sum_i F^2(x_i, z)$$

as a variable.

If Z in (7) is replaced by the variable z, and k by a variable y, then y can be considered a function of z, which approaches k as z approaches Z. Thus the behavior of y is an indicator of the nearness to Z, its best-fit value. Thus, if $F(x_i, z)$ be computed for a sequence of trial values of z, the nearness of this quantity to the observed V_i will be a measure of z's closeness to Z.

Or y can be substituted for k in other equations to give a solution. For example, for our case with only one unknown parameter Z substitute y for k and z for Z in (6), giving

$$\sum_i y[V_i - yF(x_i, z)] \frac{\partial F(x_i, z)}{\partial z} = 0 \qquad (13)$$

Since

$$y = \sum_i V_i F(x_i, z) \Big/ \sum F^2(x_i, z)$$

z can be determined by substituting a sequence of trial values of z into (13).

The method developed by *Legge* and *Rupnik* [1943] for solutions for parameters in relationships of seismic velocity to depth by the direct application of least squares is a special case of this.

Solution by comparison of $yF(x_i, z)$ *with observed values of* V—Let us consider a theoretical example to illustrate the method. Suppose that a profile across a thin, vertically polarized dike can be represented by the first-order approximation [*Nettleton*, 1941]

$$V_0 - V = 4Im(1/Z)x^2/(x^2 + Z^2) \qquad (14)$$

where m is the width of the dike, and V_0 is the value of V at $x = 0$, over the peak of the anomaly.

As the anomaly is symmetrical, we need to consider only values in the positive range of x. Suppose that $Z = 1.0$ miles, $4Im = 1.0$ emu miles, and x is taken at every 0.2 mile up to 1.6. Then from (14) we have the first two columns of Table 1.

Let us, from these data, attempt to arrive back at the values for Z and $4Im$.

For (14), $k = 4Im$, and

$$F(x, z) = (1/Z)x^2/(x^2 + Z^2)$$

Table 1 gives the quantities needed to calculate y over a range of trial values from $z = 0.6$ to 1.4 miles.

All that is now required is to tabulate values of $yF(x_i, z)$ and of Δ, their deviations from the observed values of V, and inspect them to determine Z. For convenience they are arranged in Table 2.

The value of z for which the observed values of $(V_0 - V_i)$ are most nearly reproduced is clearly 1.0 miles, giving $4Im$ a value of 1.0 emu miles, the values with which we started. Note that as the value of z passes through the best-fit value Z, Δ for each x_i passes through zero in a manner depending on the value of x_i, as shown in Figure 1. This criterion is particularly valuable in calculations, and using it, Z can generally be determined quite satisfactorily. The whole calculation can be easily programmed for the electronic computer, which can print out Table 2 over as wide a range of z as may be needed. Z can then be picked off by inspection.

Solution when $F(x, z)$ can be expanded in functions of x—The profile over a wide, vertically polarized vertical dike is given by [*Peters*, 1948]

$$(V_0 - V) = 2I[\tan^{-1}(\chi - \mu) - \tan^{-1}(\chi + \mu) + 2\tan^{-1}\mu] \quad (15)$$

where V_0, V, I are the same as in the first example, with

$$\chi = x/Z, \text{ and } \mu = m/Z$$

If we apply Taylor's expansion to (15) when $m > x$, we can write

$$(V_0 - V) \simeq 4I\left[\frac{\mu}{(1+\mu^2)^2 Z^2}x^2 + \frac{\mu(\mu^2 - 1)}{(1+\mu^2)^4 Z^4}x^4 + \frac{1}{3}\frac{\mu(3\mu^4 - 10\mu^2 + 3)}{(1+\mu^2)^6 Z^6}x^6\right] \quad (16)$$

Eq. (16) is a series of the type in (9), where $k = 4I$,

$$G_1 = \mu/(1+\mu^2)^2 Z^2, \qquad G_2 = \mu(\mu^2 - 1)/(1+\mu^2)^4 Z^4,$$
$$3G_3 = \mu(3\mu^4 - 10\mu^2 + 3)/(1+\mu^2)^6 Z^6,$$
$$H_1 = x^2, \qquad H_2 = x^4, \qquad \text{and } H_3 = x^6$$

Thus, substituting into (11), we have

$$\left.\begin{aligned}
&\sum_i V_i x_i^2 \\
&\qquad = kG_1 \sum_i x_i^4 + kG_2 \sum_i x_i^6 + kG_3 \sum_i x_i^8 \\
&\sum_i V_i x_i^4 \\
&\qquad = kG_1 \sum_i x_i^6 + kG_2 \sum_i x_i^8 + kG_3 \sum_i x_i^{10} \\
&\sum_i V_i x_i^6 \\
&\qquad = kG_1 \sum_i x_i^8 + kG_2 \sum_i x_i^{10} + kG_3 \sum_i x_i^{12}
\end{aligned}\right\} \quad (17)$$

TABLE 1 – *Values of* $\sum_i (V_0 - V_i) \cdot F(x_i, z)\gamma/\text{mi}$

y emu mi		0.43	0.68	1.00	1.40	1.94

TABLE 2 – *Values of* $V = yF(x_i, z)$ *and* $\Delta = [(V_0 - V_i) - V]$

x_i	$z = 0.6$ mi		$z = 0.8$ mi		$z = 1.0$ mi		$z = 1.2$ mi		$z = 1.4$ mi	
	V	Δ	V	Δ	V	Δ	V	Δ	V	Δ
mile	γ	γ	γ	γ	γ	γ	γ	γ	γ	γ
0.2	7	−3	5	−1	4	0	3	1	2	2
0.4	22	−8	17	−3	14	0	11	3	10	4
0.6	36	−10	31	−5	26	0	24	2	21	5
0.8	46	−7	42	−3	39	0	36	3	35	4
1.0	53	−3	52	−2	50	0	48	2	47	3
1.2	57	2	59	0	59	0	59	0	58	1
1.4	61	5	64	2	66	0	67	−1	70	−4
1.6	63	11	68	4	72	0	74	−2	78	−6

Simultaneous solution will give values for kG_1, kG_2, and kG_3, from which m, Z, and k can be obtained.

Let us take a theoretical example, with $Z = 1.0$ miles, $m = 2.0$ miles, and $k = 2.0$ emu. As before, the anomaly being symmetrical, consider only the positive range of x. From (15) we have

x, mi	0.2	0.4	0.6	0.8	1.0	1.2	1.4	1.6	1.8	2.0
$(V_0 - V_i), \gamma$	2	4	7	11	17	28	40	54	71	90

Let us now, from these data, attempt to arrive back at the original values for Z, m, and k.

Using the above values for $(V_0 - V_i)$, simultaneous solution of (17) gives

$$kG_1 = 16.7\ \gamma/mi^2; \qquad kG_2 = 1.6\ \gamma/mi^4; \qquad kG_3 = 0$$

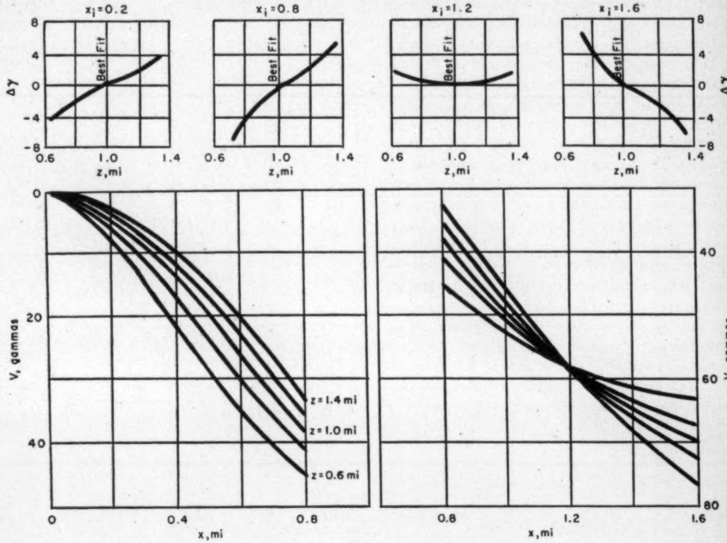

FIG. 1 – Variations of Δ with z; upper portion, manner of passage of Δ through zero as trial depth passes through best-fit value at various points on profile; lower portion, $(\sum V_iF_i/\sum F_i^2)F_i$, the second term of Δ for trial values of z; this equals V_i for best-fit z

Simultaneous solution of the three equations

$$\left.\begin{aligned} \frac{kG_1}{kG_2} &= \frac{(1+\mu^2)^2Z^2}{(\mu^2-1)} \\ \mu k &= kG_1(1+\mu^2)^2Z^2 \\ 3\mu^4 - 10\mu^2 + 3 &= 0 \end{aligned}\right\} \qquad (18)$$

gives

$$Z = 1.1 \text{ mi}, \qquad m = 2.2 \text{ mi}, \qquad k = 2.0 \text{ emu},$$

sufficiently close to the original values.

Application to gravity interpretation—The expression for the gravitational potential of a body is very similar to that for its magnetic potential. Its gravitational potential u_p at P is given by [*Heiland*, 1946, p. 144]

$$u_p = G\rho \iiint \frac{1}{r}\, dV \qquad (19)$$

where G = the gravitational constant, ρ = the density of the body, assumed to be uniform, and dV, r and limits of integration are the same as for (1). Comparing (1) and (19), we see that any least-squares methods developed for magnetic equations can also be applied directly to gravity equations.

Summary and conclusions—Least-squares methods have previously been applied in geophysics chiefly in the reduction of observations, and to such calculations as obtaining residuals and derivatives.

In the present paper it is shown that the equations of magnetic and gravity interpretation are such that for all bodies a solution for the parameters of the equation of the corresponding anomaly field is possible by least squares. In practice a certain amount of simplification is required unless the calculations can be programmed for the electronic computer, making it possible to treat quite complex solutions.

Synoptic and Climatological Problems Associated with the General Circulation of the Arctic

JEROME NAMIAS

Abstract—Reasonably complete analyzed maps at sea-level, 700-mb, and 200-mb over the past decade have made possible a much improved picture of normal characteristics of the general circulation over polar regions including the interplay between synoptic and planetary scale patterns. Charts believed to represent fairly close approximations to long term normals are presented for January, April, July, and October, and an attempt is made to associate prevailing circulations with characteristics of the underlying surface, with season, and with type of synoptic development.

Large climatic fluctuations in circulation over periods of a month to a season are described and illustrated.

The short-period (day to day) variations over the Arctic and the associated prediction problems appear to be of the same nature as those of temperate latitudes and are thus amenable to present numerical methods. Longer-period fluctuations pose a much more difficult problem.

Introduction—During the past ten years the unprecedented accumulation of meteorological data at the surface and aloft over Arctic regions has led to a reasonably good picture of the synoptic meteorology and climatology of the Arctic atmosphere's general circulation. Earlier speculative interpretations of fragmentary information, involving frustrating efforts to interpolate in the horizontal and vertical, have now been replaced by a more solid framework provided by real data. These data, available for about a decade, cover much of the Arctic expanse and reach up into the substratosphere. While these newer data do not meet the requirements of many meteorologists, nevertheless, considering phenomena of ordinary synoptic scale and especially the scales of hemispherically interactive centers of action, the Arctic is relatively well represented by observations, certainly much more so than other areas of global meteorological importance like the Pacific.

From the new observations it turns out that many meteorologists of earlier generations might have made better inferences of the synoptic and climatological characteristics of the Arctic had they envisaged systems of greater similarity with those of the more familiar temperate latitudes, instead of seeking quite different models. It is now abundantly clear that cyclones and anticyclones traverse the Arctic in much the same fashion as in temperate latitudes, and upper level troughs, ridges, cyclones, and anticyclones, with dimensions and movements comparable to those of temperate latitudes, are synoptically common and transitory. As in temperate latitudes, pronounced autocorrelation exists from day to day; from week to week; and, to appreciable extent, from month to month. Indeed, the assemblage of several years of data suggests the existence of climatic fluctuations of the same order as those found elsewhere. In short, the atmosphere's general circulation over the Arctic appears to differ from temperate latitudes mainly in the statistics and not the kind of circulations. One may question, therefore, the degree of specialization indicated by the title, Arctic Meteorologist. On the other hand, the specialization leading to the title Tropical Meteorologist is more justifiable, for synoptic characteristics of the tropics are of another kind and scale from those of temperate latitudes.

The following remarks and illustrations are designed to highlight some of the circulation features of the Arctic gathered in the course of preparing hemispheric analyses and forecasts during the past decade. An attempt will be made to associate the most recent best estimates of the normal seasonal circulation patterns over Arctic regions with synoptic phenomena and thus assist in their explanation.

The normal circulation in the troposphere and lower stratosphere—In a recent paper [*Namias*, in press] the author displayed eight-year averages of sea-level pressure and 700-mb height over the Arctic for four months and compared these with earlier estimates of the 'normal,' particularly those made by the *U. S. Weather Bureau* [1952] and by *Baur* [1929]. The results of this study suggested that for most purposes the normal patterns of circulation of the lower troposphere over the

Arctic are reasonably well established, so much so that it is difficult to detect whether differences between the normal and averages of periods of five to ten years reflect transitory climatic fluctuations or erroneous earlier estimates of the normal. At any rate, while differences between such periods are undoubtedly statistically significant, they do not materially alter the large-scale aspects of the patterns. Thus, changes observed from one day, week, or month to the next are so overwhelmingly large that such 'errors' of the normals do not seriously interfere with current synoptic practices.

The eight-year averages to which reference is made are reproduced in figures 1 to 4, along with similar new charts for the 200-mb level. The sea-level and 700-mb charts were constructed from interpolations from twice-daily synoptic analyzed charts at closely spaced intersections of latitude and longitude. This method has the advantage of smoothing and detecting errors at the source of the daily map. The 200-mb charts for January and July, on the other hand, were computed as weighted means from the British Meteorological Office Average Charts [*Heastie*, 1955, 1956] for the years 1949–1953 and from U. S. Weather Bureau and Air Force daily 200-mb manuscript analyses during 1954–56. The only readily available data for the April and October 209-mb charts were extracted from U. S. Weather Bureau and Air Force daily analyses for 1951–56. The area 110°E to 20°E was not adequately covered during this period and is therefore left blank.

Figures 1 to 4 hardly require lengthy description for it is felt that meteorologists may easily draw from them whatever information is desired. However, there are certain primary features which call for explanations, and attempts in this direction stemming from years of synoptic practice shall be made with no illusions concerning their completeness. It is obvious that only when the observed circulations are exactly reproducible by quantitative methods or model experiment, a completely satisfying explanation is at hand. Perhaps the following remarks may suggest experiments or ideas for more quantitative assessment.

One prominent feature of the January upper-level charts which calls for explanation is the tri-cellular circulation in northern latitudes, which, to a considerable extent, is reflected as high up as 200-mb. While the presence of three waves in upper temperate latitudes has been known for many years, the existence of three closed cells in mid-troposphere at the tops of the

planetary troughs emerges as a somewhat surprising feature. One might ask why such waves appear on the normal map, why they are where they are, and why the troughs are surmounted by closed cyclonic cells. Answers to the first and second questions must be sought partly in the geographical differences underlying the atmosphere's general west to east flow [*Rossby*, 1939; *Charney* and *Eliassen*, 1949; *Bolin*, 1950; *Smagorinsky*, 1953]. During winter the off-shore heating of cold air thrusts from the Asiatic monsoon anticyclone and the associated coastal cyclogenesis undoubtedly play a major role in creating a mid-tropospheric trough. To a lesser extent a similar trough tends to develop along the east coast of North America, but also an apparently strong forcing influence is the Rocky Mountain chain which, underlying the prevailing westerlies, creates a trough to the lee. These two 'forced' perturbations in the westerlies, the west Pacific and eastern North American troughs, are apparently sufficiently close so that the normally fast prevailing westerlies of January can frequently support both with little mutual interference. Eastward from eastern North America, however, the span between these two troughs is so great that the insertion of another perturbation, the European trough, becomes necessary to produce a dynamically stable system. In other words, as *Bolin* [1950] indicates, the European trough may be responsive to the flux of vorticity from the trough over eastern North America.

The closed cyclonic cells at the tops of these three troughs appear to be associated with the normal fields of baroclinicity of the atmosphere, perhaps in the following manner: It is now realized from the work of *Starr* [1954] and his colleagues that synoptic-scale phenomena of the weather map (the cyclones and anticylcones) must be introduced in order to explain the transfers of momentum, heat, and energy necessary to maintain the mean general circulation. The fundamental planetary trough systems of the general circulation more or less predispose the areas where these disturbances form and develop. Hence, off the east coasts of Asia and North America, the wave cyclones develop and move northeastward, feeding on the great baroclinicity established over the area between cold continent and warm ocean. These rapidly occluding disturbances eventually form the Aleutian and Icelandic lows, and appear in the mid-tropospheric wave patterns as strong maxima of cyclonic curvature (vorticity) in the Aleutians and east of Greenland. The sharp cyclonic bends in the 700-mb contours in these areas reflect vorticity sources generated by the intensifying cyclones. As a result, the upper level warm sector currents are frequently forced to curve from southeast toward northwest over the Bering Sea and eastern Siberia and also over Greenland and the Davis Strait. These currents, in turn, help to produce cut-off cold lows, whose statistical summations show up on the normal charts as the Kamchatka and Baffinland cyclones. Obviously, the cutting off of the tops of the two primary troughs automatically establishes the third cut-off low at the top of the Novaya Zemyla trough.

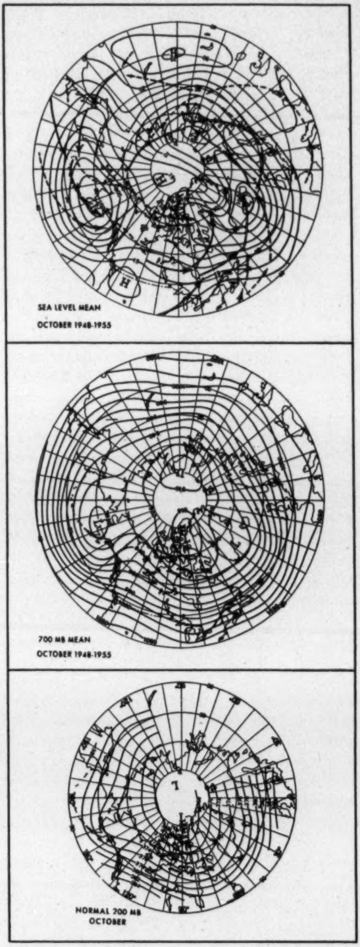

FIG. 4 – Same as Fig. 1, but for October

Synoptically, the process just described is a rather common wintertime phenomenon. Warm high-level ridges, and occasional anticyclones, frequently migrate westward and northwestward from the Aleutians and eventually make juncture with the Siberian anticyclone. Similarly, in the mid-troposphere warm pools cross westward and northwestward from Spitzbergen and Iceland, associated with depression of the Polar upper level vortex and not infrequently with a train of wave cyclones moving from southeast to northwest along a front with inverted air mass distribution.

The displacement with elevation of the primary sub-polar low systems in January indicates that in comparison to the Kamchatka low, the Icelandic low has a much greater portion of its westward displacement with height concentrated below 700 mb, a fact probably reflecting the greater asymmetry of geographical influences in eastern Asia than over northern Canada and Greenland. In other words, the stronger and deeper radiational cooling over northeast Siberia relative to the oceanic heating to the east effects a continued westward displacement with elevation of the low pressure center, while cooling by the Greenland Plateau (and frozen Davis Strait) results in a more or less thermal symmetry around the Baffinland low at the 700-mb level. Of course, normal isotherms at the 700-mb surface show this difference, a necessary condition from hydrostatic considerations.

The April charts (Fig. 2) show striking differences from January, perhaps the most noticeable of which is the marked relaxation in gradient at all three levels. This relaxation is due mainly to the weakening of both subpolar cyclones. At the same time the character of the Arctic Basin sea-level circulation becomes anticyclonic in character so that north of 70° a net rise of three to four millibars has occurred. Aloft, the three-celled structure is eliminated and replaced by a circumpolar vortex with southward trough extensions, two of which are in the primary subpolar cyclone areas. Probably in response to the slower zonal wind speeds at high latitudes, the number of waves around the hemisphere has increased from three to four, a new trough having emerged in the Gulf of Alaska. The filling of the mean Aleutian and Icelandic lows is associated with the reduced normal field of baroclinicity found in April along and off the east coasts of Asia and North America, so that northeastward moving disturbances, while still very frequent, do not have the supply of energy for development that they have in January. Besides, in April the frequency of blocking anticyclones at high latitudes is well near its May maximum as *Rex* [1950] indicated, so that the sub-polar lows are more often replaced by highs than in January. The increase in blocking activity is undoubtedly also associated with the increase in pressures over the entire Arctic Basin, although the physical reasons for this increase are not too clear. The author [*Namias*, 1950] prefers to ascribe the increased high latitude anticyclogenesis in spring to the relatively cold water and extensive ice areas found there, especially at this time of year. These cold areas are preferred regions for anticyclones and anticyclogenesis. Perhaps this tendency is due to the pronounced vertical stability observed over such areas. As *Wexler* [1943] pointed out, stability favors less leakage from the shallow friction layer at the bottoms of the anticyclones than instability over warm areas where the friction layer is deeper and the outflow greater. The extension of the Canadian-Arctic anticyclone to the relatively cold Hudson Bay in April seems to be a good example of this effect.

In July the normal upper air patterns are somewhat similar to April, at least as far as the central Arctic vortex and the troughs near Kamchatka, in the Gulf of Alaska and over eastern Canada are concerned. However, a tendency to a five-trough system now appears with the emergence of the Novaya Zemyla trough and suggested retrogression of the April European trough to the British Isles-Iceland area. The initiation of the new trough dominating eastern Russia and western Siberia appears to be a response to the marked decline in westerlies which sets in from spring to summer over the Eurasian area. The falling away of sea-level pressures from April, over the Arctic, is associated with the warming of the lower troposphere, since heights at the 700-mb level show an appreciable rise during this period. This rise is somewhat more pronounced over the peripheral land areas, as one would expect, so that a zone of thermal contrast becomes established near the rim of the Polar Basin which appears to give birth to frequent cyclones and peripheral cyclone movements (note cyclone paths in Fig. 3). Of course, frequent cyclones without strong anticyclonic counterparts result in the average low sea-level polar pressure observed in July.

Another interesting change in the July maps relative to April is the complete obliteration of the eastern (Gulf of Alaska) lobe of the Aleutian low. This appears to be due to the lack of a comparable baroclinic field between Alaska and the Gulf of Alaska in July compared to April. In other words, the heating in the interior of Alaska wipes out the strong thermal contrast southward

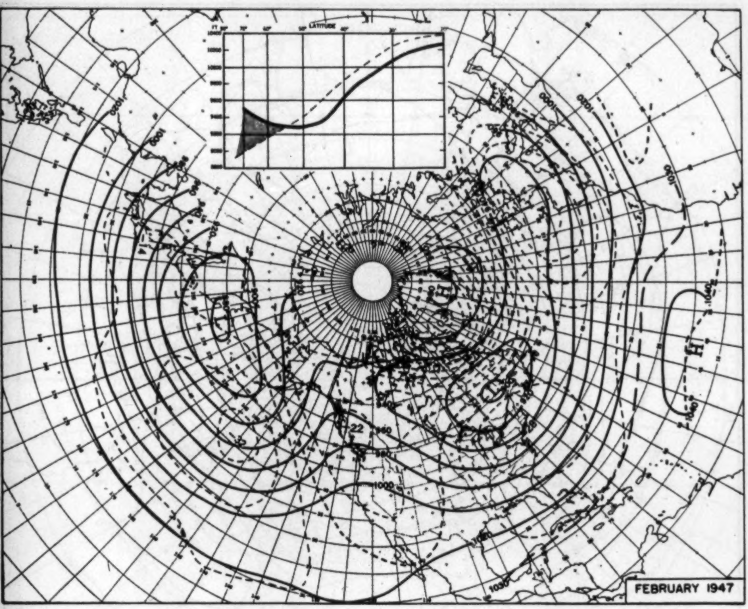

FIG. 5 – Mean 700-mb contours (solid) and departures from normal (broken) for February 1947

to the sea which is so effective in encouraging rejuvenation of old secondaries during winter and spring [*Winston*, 1955].

By October (Fig. 4) the wintertime type of pattern has already set in over the entire Arctic. The vigor of the circulation is indicated by the markedly strengthened gradients. The major characteristics of the three-wave and tricellular mid-tropospheric pattern show up clearly. However, the Aleutian low, both at the surface and aloft, is more in the nature of a single than a double center, so that the Kamchatka low, so predominant in January, is merely a cyclonic appendage to the center in the Aleutians. These differences between October and January show up strongly in the mid-troposphere (700-mb) and sub-stratospheric (200-mb) levels where there is almost an out-of-phase picture between these two seasons. This change, which in essence is a retrogression from October to January of the major trough-ridges system north of latitudes 55°N to 60°N in the Alaskan-Bering Sea and eastern Siberian area, is not readily explained. Perhaps it is associated with the stronger baroclinicity and cyclonic developments off Asia in January which permit cold occluded (and semi-stationary) lows to develop sooner and, hence, farther westward. This, in turn, is probably also associated with the stronger northeastward thrust of the Siberian high in January so that the strengthened easterlies north of Kamchatka retard the eastward motion of cyclones to the south. On the other hand, this difference may be induced by the different geographic influences on the higher latitude westerlies in October relative to January. At any rate, the strong asymmetry of the middle and upper tropospheric contour fields reflected in the great January displacements with elevation of the Aleutian Low seems to be absent in October when the 700-mb and 200-mb troughs are almost vertically posed over the surface cyclone.

At still higher levels than 200 mb, data should, in a few years, become sufficient to obtain a fair

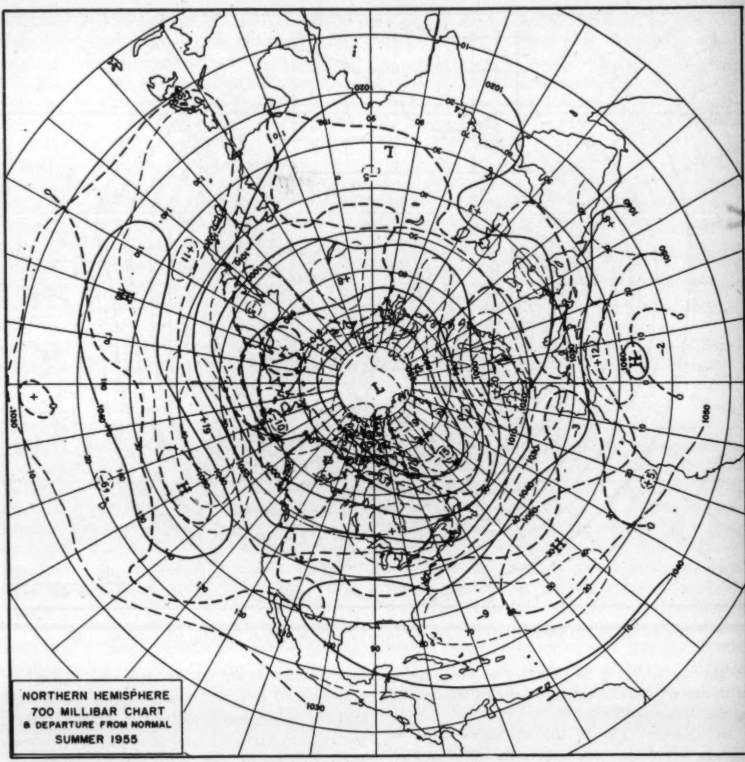

FIG. 6 – Same as Fig. 5, but for summer 1955

climatological picture of the polar night jet on a hemispheric scale. At present, it is possible to obtain only fragmentary information [*Lee* and *Godson*, 1957] of its seasonal variation, habitat, and strength. While it is tempting to draw climatological inferences from short periods of record, the great variability in meteorological elements between years must be borne in mind. Indeed, even for sea-level and 700-mb charts, for which a much more extensive source of data exists, there are suggestions that the eight-year period 1948–55 may have been abnormal in the sense that pressures were too high relative to a longer period average over the Baffinland-Davis Strait-Greenland area. (These persistent abnormalities, especially over periods of a year or two, form one of the central problems of long-range forecasting and should be kept continually in mind by students who plan to interpret the new IGY Antarctic data.)

Shorter-period climatic fluctuations—While data are inadequate to detail climatic fluctuations in the Arctic circulation of the order of years or decades, they are adequate to afford some insight into seasonal, monthly, and shorter period fluctuations. Perhaps one of the most striking aspects of Arctic circulation patterns is the tendency of a particular type to persist in broad-scale from day to day, and to persistently recur in the same season after only brief interruptions. There are, of course,

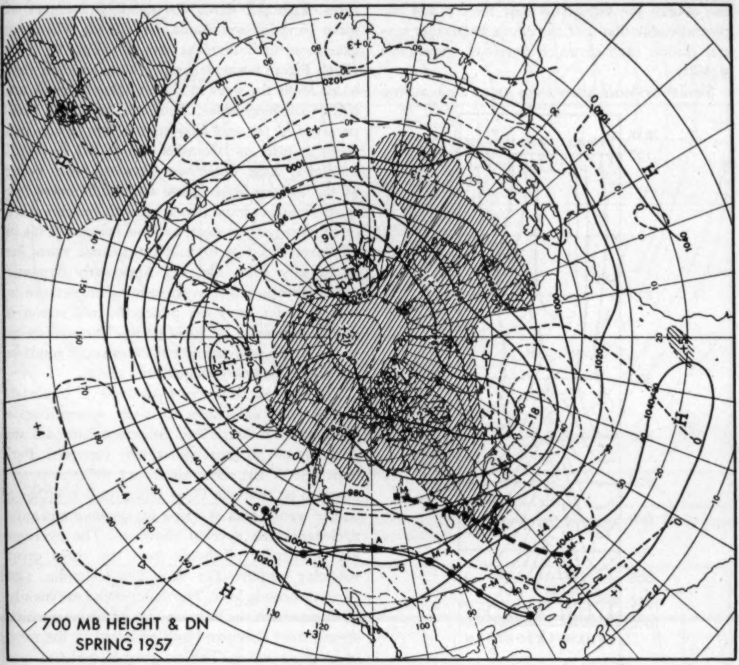

FIG. 7 – Same as Fig. 5, but for spring 1957; heavy arrow-pointed lines running through United States denote monthly course of negative (open) and positive (solid) anomalies appearing on maps for individual months, denoted by letters

synoptic scale variations associated with the transit of cyclones and anticyclones, but these appear to be governed by a larger scale and quasi-persistent circulation pattern, which may differ considerably from one season to the same season of another year. As a result of the serial correlation in daily, weekly, and monthly circulations, the magnitude of departures from normal (or from a long-period average) over the Arctic are surprisingly large. Examples of such anomalies at the 700-mb level for three periods, February 1947, the summer of 1955, and the spring of 1957, are shown in Figures 5, 6 and 7. Figure 5 illustrates a case where the cyclonic activity normally present over the polar cap was replaced by a great anticyclone, so that the sea-level prevailing westerlies of temperate latitudes were displaced about 20° southward of their normal latitude [*Namias*, 1947]. Figure 6 shows an unusually strong upper-level cyclone over the Polar Basin girdled by several strong positive anomalies associated with a northward displacement of the sub-tropical highs. The resultant strong westerlies along the rim of the Polar Basin were associated with an unusually high frequency and intensity of cyclones. Figure 7 illustrates an extensive excess mass over polar regions and apparently compensating deficits in the subpolar cyclones. On this chart are also indicated the paths of certain anomaly centers extracted from overlapping 30-day mean charts. The parallelism of these paths with the isopleths enveloping the polar anomaly suggests that the latter may have exerted a steering influence [*Clapp*, 1952], and such Arctic influences might be highly important for 30-day prediction.

From such routine happenings over the Arctic one obtains the impression that there is not one general circulation over the Arctic but rather several modes, each of which possesses remarkable stability.

Similar evidence arises from upper air temperatures. Figure 8 shows the monthly averages of some 10 years over Thule, Greenland. When one examines the individual months (Fig. 9) from which Figure 8 was derived, it becomes clear that at all levels the same month of different years are highly inhomogeneous. Thus, the minimum temperature in the mid-troposphere over Thule can occur as early as December and as late as April. Similarly, large differences between years occur at the 200-mb level. These latter differences frequently appear to be associated with the curvature of the flow pattern aloft, cyclonic being cold (as in January 1956, Fig. 10) and anticyclonic warm (as in January 1953, Fig. 11). Apparently dynamic considerations are of overwhelming importance in high latitudes, especially during the cold season, a point emphasized by *Riehl* [1950]. The sensitivity of the Arctic to dynamic influences could result in rewarding studies of singularities there.

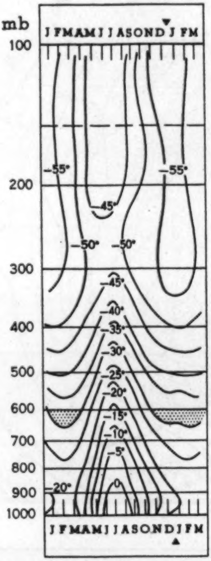

FIG. 8 – Average monthly temperatures over Thule, Greenland, for the ten-year period 1947–1956

The synoptic short-period problem—As indicated earlier, the differences between synoptic-scale phenomena of Arctic and temperate latitudes are probably not as great as formerly supposed. Perhaps one of the more significant differences appears to be that the Polar Basin itself is either a sort of transit area or a sink for cyclones and anticyclones which develop elsewhere. The cyclones are principally off-shoots from the three great subpolar centers: The Aleutian, Icelandic, and Novaya Zemyla lows. The anticyclones are mainly off-shoots from the Siberian high or systems which spread from Greenland and eastward in the form of blocking waves. The entrance of cyclones into the Polar Basin is especially favored when blocking or high latitude anticyclogenesis is pronounced,

for the deep warm highs block the normal eastward course of storms and steer them more northward. This type of activity is especially common with the Davis Strait and Bering Sea storm systems, and also with systems occasionally forced northward in response to the invasion of northern Europe by the Siberian high. On their western sides the deep blocking anticyclones provide a long fetch for warm air masses so that sharp meridional or even NW-SE oriented fronts are established. This orientation makes it difficult for the inexperienced analyst to trace the structure and continuity of cyclones which rotate counterclockwise around the northern periphery of a deep upper level vortex suppressed well to the south of normal.

Both the cyclonic systems discussed above, and the break-off anticyclones from the Siberian high, appear to be instigated by or at least closely associated with imbalances of the high latitude planetary wave systems which often respond in a manner suggestive of redistribution of vorticity. Thus, the results of 24- and 48-hour barotropic prognoses by electronic computer at Suitland, Maryland, the United States show that for large areas of the Arctic the errors are not greatly different than they are for temperate latitudes and, moreover achieve a skill at least equal to those of conventional forecasters [*Staff members, JNWP*, 1957]. Figure 12 shows the mean absolute errors for such 48-hour forecasts made daily during April and May 1957. Aside from the large errors over and north of eastern Siberia, which are largely boundary errors [*Cressman* and *Hubert*, 1957], the success is quite comparable to elsewhere. The extension of the grid to cover a larger area of the hemisphere will undoubtedly result in still better numerical predictions over the Arctic. Here again there appears to be no reason to treat the Arctic separately from temperate latitudes. Of course, this does not imply that special features of Arctic weather and climate should not receive careful study. But it indicates that more complete solutions relating to temperate latitude circulations, perhaps obtainable with the help of machine prognosis, may also be solutions for the Arctic atmosphere.

In summary, the principal synoptic and climatological problems of the Arctic atmosphere as seen today appear to be not so much with determination of the average or normal circulations, although further data are always welcome, but rather with the explanation of the seasonally different patterns and particularly the stable though anomalous patterns that arise during particular months. This is in essence the dynamic climatology of the circulation. Of course, the gathering and summarization of statistical properties of the Arctic atmosphere, together with descriptive studies will be helpful, both practically and toward a better physical understanding. Similarly, case studies detailing the structure of the Arctic air masses and fronts will be helpful.

The Accuracy of Wind-Speed Estimates at Sea

CHARLES F. BROOKS AND ELEANOR S. BROOKS

Abstract—Most wind reports at sea come from merchant ships without anemometers. The Beaufort scale is used, the units of which are now defined principally in terms of sea disturbance. A study of 1315 pairs of measured and estimated winds made on U. S. weather ships shows that the estimated speeds corresponded to the measured within 1–3 knots (same Beaufort number) in 60 pct of the cases; 28 pct were underestimated and 12 pct overestimated. The greater frequency of underestimates than of overestimates is apparently owing mainly to the fact that the anemometers (at 20–30 m) on the weather ships are higher than the (10 m) elevation for which the speed equivalents of the Beaufort scale were established, but partly also to the extra mileage of the anemometer owing to the rolling and pitching of the ship.

Changes in wind speed occur so often that lag in the reaction of the sea is the most common cause of error in estimates. Another source of trouble is the sea—air temperature difference, a cold wind relative to the sea producing larger waves than a warm wind. Decreasing winds that are also cold are especially likely to be overestimated, and increasing ones that are warm, underestimated.

On weather ships and some merchant vessels, wind speed at sea is determined by anemometer. Merchant ships without anemometers now report winds in knots converted from Beaufort. How do measured and estimated speeds compare? The comparison is somewhat troublesome. We have no standard true wind speed, such as might be obtained from a fixed anemometer. We are comparing winds at different levels, using two methods subject to different types of errors. Discussions of the problem by meteorologists of eight countries were recently published by the *World Meteorological Organization* (*WMO*) [1955, pp. 19–27].

Anemometers at sea—Anemometers on U. S. weather ships are placed at an elevation of 20–30 m on the mast or yard-arm, to minimize the influence of the obstructing bulk of the ship. Since the Beaufort estimates are officially matched against winds measured at 10–15 m, the measured winds at 20–30 m should exceed the official equivalents on the average by about three to five per cent, according to *Roll* [1951].

Over-registration by cup anemometers is caused by gustiness; it is also favored by the extra miles of air the anemometer travels owing to the rolling and pitching of the ship, which is magnified high on the mast [*WMO*, 1955, pp. 20–22]. On the other hand, in very light winds the anemometer may fail to start or keep going. Nevertheless, anemometer speeds are obviously more accurate than estimates from sea disturbance, and may be used with some assurance for determining the errors of the latter.

Estimates of wind speed—The Beaufort scale was based originally on the speed of an ideal sailing frigate with all sail set (force 0–4), or on the amount of sail it could carry (force 5–12). When sailing ships were no longer in common use, sea disturbance was correlated with the Beaufort rating of the wind; also Beaufort force B equivalents in knots have been standardized from readings of anemometers at an effective height of 10–15 m above sea level [*WMO*, 1950–56]. For a detailed historical account and critique, see *Verploegh* [1956]. A revised standard proposed by *Verploegh* [1956], based on two sets of new data coordinated with seven older sets, has recently been recommended by the Commission for Maritime Meteorology for adoption by the *WMO* [1957, pp. 29–30].

Wind estimates may vary considerably among observers. On two trans-Atlantic voyages author C. F. B. made 57 careful estimates at regular ship observation times. The ships' observers estimated the same force as C. F. B. 36 times, one Beaufort different, 16 times, and two different, five times. *Lisitzin* [1948] checked Finnish light ships. One had five observers from 1921–1940, and their average reports ranged from 2.4 B to 3.7 B, while other light ships showed no comparable changes.

Wind speed at sea, when not changing rapidly, can be estimated by the amount of sea disturbance [*WMO*, 1950–56; *Burgess*, 1950; *U. S. Weather Bureau*, 1954], if due account is taken of several modifying factors [*Kirk*, 1948; *Roll*, 1950], including whether the wind is warmer or cooler than the water.

The temperature factor in estimates—It has long been known that winds colder than the sea raise bigger waves than those warmer and of the same speed [*Humphreys* and *Brooks*, 1920]. C. F. B. [*WMO*, 1955, p. 20] has cited cases of a wind of 3 *B* over a glassy sea of cold water and of another of 5 *B* making large waves with many white caps on stretches of warm water, but only medium waves and few white caps, of normal 3–4 *B* size on an intervening zone of cold water.

Roll [1951] found that when the air was 1 C deg warmer than the sea, the wind at 20 m height had to be 7.5 m/s to provide the actual surface wind of 3 m/s required to raise waves of 3 *B* grade; with no temperature difference, a wind of 5.8 m/s was sufficient; but when the air was 1 C deg colder there was enough vertical mixing to raise a 3 *B* sea with a wind at 20 m of only 4 m/s. *Roll* [1951] has now presented data from North Atlantic weather ships demonstrating numerically that "with wind of equal force waves will become higher and steeper in case of cold air than they will become in warm air." With winds of 13–37 k (4–8 *B*) waves averaged 23 pct higher and 14 pct steeper when the air was 6.7 C deg (12 F deg) colder than when 2 C deg (3.6 F deg) warmer than the sea.

Fleagle [1956] confirmed Roll's findings, from a study of 150 cases observed at Station Hotel, 36°N, 70°W. He took care to eliminate the factor of varying fetch.

Colder water produces a more or less stable layer of chilled air which inhibits wind thrusts to the surface, especially in winds not exceeding 4 *B*; it cools the entire turbulent layer of air and thereby reduces the general turbulence and therefore the strength of the thrusts reaching the cool protecting layer of air [*Humphreys* and *Brooks*, 1920; *Båth*, 1949; 1951, pp. 295–304; *Bernasconi*, *Bossolasco*, and *Dagnino*, 1952]; and, lastly, it increases the vertical gradient of wind speed, so that the wind at the surface will actually be considerably less than that on the mast [*Roll*, 1952]. There is an additional factor, though usually a small one, namely, the density of the air: thrusts of warm, humid air under low atmospheric pressure are less powerful at the same speed than those of cold, dry air under high pressure. The viscosity of sea water, which varies with its density, is also a minor factor. Warm winds over a colder sea, therefore, tend to be underestimated and vice versa.

A NEW STATISTICAL STUDY

The relationship between wind estimates and measurements was investigated by us in a series of 1315 observations of wind speed made for the purpose from Feb.–Aug. 1951 on eight different U. S. weather ships at and near Station Dog in the North Atlantic (lat 44°N, long 41°W). Conical cup anemometers were employed, mounted on masts 70–100 ft (20–30 m) above the sea. Conical cups over-register less than hemispherical ones in a gusty wind [*Scrase and Sheppard*, 1944].

GENERAL RELATIONSHIP

Estimated versus measured speeds for each force Beaufort—Table 1 shows wind measurements by knots for each estimated force Beaufort. Column 2 shows wide scattering. Indeed, winds of 25 knots were estimated all the way from 3 *B* to 8 *B* but were most frequently called 6 *B*. Thus, 25 knots was classified as 6 *B*. Similarly, 10 knots, which ranges from 2 *B* to 6 *B*, was assigned to 3 *B*. Column 3 divides the measured speeds among the several Beaufort numbers at which they were most frequently estimated, as just described. Our data conform more closely to the previous official Beaufort scale in general than to the proposed new

8	219	15	81	4
1–8	1315	28	60	12

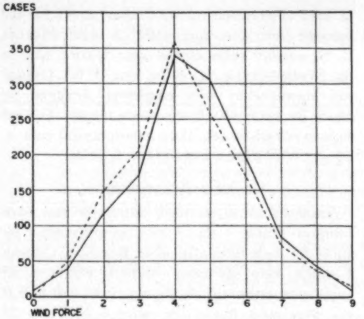

FIG. 1 – Numbers of cases of wind speed by Beaufort number out of a total of 1315; solid line, converted to *B* from anemometer readings; dashed line, estimated from sea disturbance

standard, but show measured values a little high for the force at which they were estimated, especially in the middle of the scale.

Verploegh [1956], on the contrary, found measured values too high for light winds and too low for heavy winds, the middle of the scale showing the best agreement. His scale is adjusted for anemometers at a height of 10–15 m; ours were at 20–30 m.

It was hardly practicable to assign a definite average value in knots to each force *B* in our series because the anemometer data were not recorded too closely. Observers appeared to favor multiples of 5, and, to a lesser extent, even over odd values. For example, a tabulation of four sets of data from four different ships showed the following distribution: 18 knots, 31 cases; 19 knots, 18 cases; 20 knots, 53 cases; and 21 knots, 15 cases.

Estimated versus measured speeds for each set of observations.—Table 2 and Figure 1 show clearly that estimated wind speeds E were more frequently below, than above, the measured M. Measured and estimated force agree in 60 pct of the cases, however, and the difference exceeded one force Beaufort in less than five per cent of the cases. *Verploegh* [1956, p. 14] found that if measured velocities are considered fixed, the error in estimates may amount to 0.4 *B* in ⅔ of the cases. Night observations showed about the same degree of accuracy as those made by day.

SOURCES OF ERRORS IN ESTIMATES

Errors of estimation when wind speed is changing—To analyze further the causes of disagreement, we compared estimation of changing winds with estimation of well-established winds for measured 4 *B*, the most frequent force. A case was counted as changing if 4 *B* had not been recorded at either of the two previous observations. Observations were taken at three-hour intervals. By contrast 4 *B* was counted as well established if that force had been recorded at both previous observations. The results are shown in Table 3. Naturally, established winds are most likely to be correctly estimated.

TABLE 3 – *Effect of changing, measured wind speed on estimated speed*

Wind character	No. of cases	E < M	E = M	E > M
		pct	pct	pct
4 *B*, changing winds	137	28	49	23
4 *B*, established winds	70	13	87	0
All winds (from Table 2)	1315	28	60	12

Because of the overall tendency for estimates to be lower than measured values, most profiles in these figures are unsymmetrical; that is, the underestimates exceed the overestimates. The profile for all winds is intermediate between those for 4 *B* changing and 4 *B* well-established.

This sampling encouraged a more extended test of changing winds, with less narrow limits. Every wind was classified as 'decreasing,' 'no change,' or 'increasing,' according to whether the measured force Beaufort at the preceding observation was less, the same, or more. Wind speed only was considered. There were 373 cases of 'decreasing,' 550 of 'no change,' and 384 of 'increasing'; 8 were indeterminate, being the first ones in each of the eight series. The estimated values clearly show a lag effect (Fig. 2).

When judging from sea disturbance, there is a tendency to underestimate rising winds and to overestimate decreasing winds. *Verploegh* [1956] writes of the retardation with which the sea follows changes in the wind field: "After a stormy period normal wind velocities which are usually estimated 0.5 to 2 knots too low are now estimated too high."

Errors of estimates when sea and air temperatures differ markedly—Sea–air temperature differences also affect wind-speed estimates. It is generally recognized that a wind warmer than the sea tends to produce smaller waves than a wind of equal speed which is colder than the sea. Since wind speed is estimated from sea disturbance, this favors underestimates of warm winds and vice-versa. In 82 out of 1315 cases (six per cent) the air was at least 3.6 F deg. (2 C deg) warmer than the sea. Of these 82 cases, 30 were concentrated in one week (July 31–Aug. 6). In other locations, for example, over the Labrador current, greater contrasts might occur. More often the air is colder than the sea, and by a larger amount; for example there were 196 cases (11 pct) of air at least 9.0 F deg (5 C deg) colder than the sea.

Figure 3 shows the effect of sea–air temperature differences on Beaufort estimates. The record for warm winds (Fig. 3) very closely resembles that for all winds (Table 2). The number of cases (82) is somewhat small, however, especially since 36 came from one ship and 31 (86 pct) of these are correct estimates. The other seven sets show 43 pct underestimates, 48 pct correct, and 8 pct overestimates. The cold winds show a slight excess of overestimates.

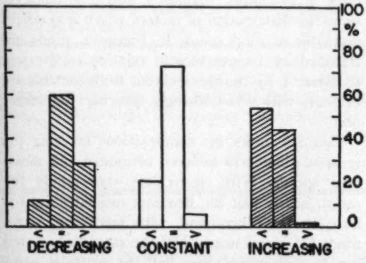

FIG. 2 – Effect of decreasing or increasing wind (all speeds) on estimated force derived from the disturbance of the sea surface

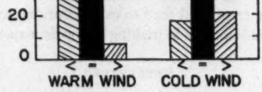

FIG. 3 – Effect of relative temperatures of sea and air on estimates of wind speed from the disturbance of the sea surface

TABLE 6 – *Average wind speed as measured for cases when estimated wind was 5 B*

Category of air-sea temperature contrast at 5B	Cases	Wind speed measured
		knot
General average	250	20.5
Air 3.6 F deg or more warmer than sea	13	20.6
Air 9.0 F deg or more colder than sea	43	19.7

More cases can be obtained by averaging all sea–air temperature differences, as in the sample in Table 4 which is restricted to winds estimated at 4 *B*, the most frequent force. In this group of cases, when estimates exceed the measured wind the winds average definitely colder than the sea. Air temperatures are taken at a height of about 20 ft above the water.

To bring out temperature control more clearly, we tabulated 62 cases of established winds measured 5 *B*. These are summarized in Table 5.

Classification by temperature difference gave consistent but not definitive results (Table 6), as the opposite extremes of sea–air difference showed an average difference of only about one measured knot in the winds involved (20.6 and 19.7 knots, respectively). *Verploegh* [1956, p. 15] did not find any systematic differences in equivalent velocities at 7 m for unstable and stable conditions. Apparently, 7 m is so near the surface that the effect of a cold sea in damping wind speed is already strongly felt.

Joint effect of changes in wind speed and sea–air differences in temperature—Now let us look again

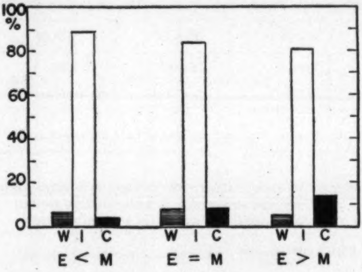

FIG. 4 – Relation of estimated to measured wind subdivided according to the temperature of the wind relative to that of the sea surface; the limits of the temperature classes are: warmer (W), at least 3.6 F deg (2 C deg) warmer; intermediate (I), between less than 3.6 F deg warmer and 9.0 F deg colder; and colder (C), at least 9.0 F deg (5 C deg) colder

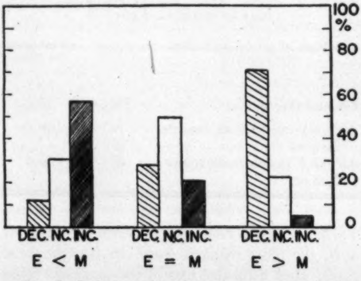

FIG. 5 – Relation of estimated to measured wind subdivided according to the trend in wind speed since six hours earlier; the wind-speed classes are: decreasing (DEC), a decrease of at least one Beaufort number; no change (NC), no change in Beaufort number; and increasing (INC), an increase of at least one Beaufort number

at the combined effect of changing wind speed and contrasts in air and sea temperature. In Table 2 and Figure 1 a general tendency for measured values to exceed estimated was shown, and we indicated that this was probably caused by the height of the anemometer being greater than that for which Beaufort numbers were standardized and to the extra mileage of the anemometer owing to the rolling and pitching of the ship. After our analysis of the sea versus air temperature factor it is now clear that the tendency for measured to exceed estimated winds cannot be ascribed to

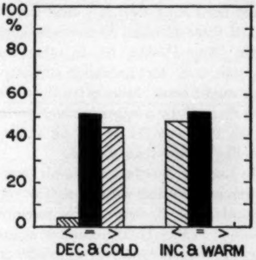

FIG. 6 – Combinations showing the greatest differences between estimated and measured wind speed

winds being warmer than the sea, because relatively cold winds are more frequent in this group.

Changes in wind speed occur so often that lag in the reaction of the sea is a common source of error in estimates. Figures 4 and 5 attempt to show the distribution of factors which may affect estimates of wind speed. In Figure 4, winds are classified by temperature in relation to the sea, in Figure 5, by change of speed. Both controls are evident, with wind changes playing the larger part.

Figure 6 shows the combinations favoring the greatest differences between estimated and measured speeds. With decreasing, cold winds (67 cases), nearly half the Beaufort estimates are too high; on the other hand, with increasing, warm winds (21 cases) nearly half the estimates are too low. In each group about half the estimates agree with the measured Beaufort. The number of cases is hardly adequate.

The best agreement (87 pct) between estimates and measurements appears in Table 3, based on 70 cases of well-established winds, force 4 *B*. It so happens that this group contained four winds 3.6 F deg warmer than the sea, and only two winds 9.0 F deg colder, all listed among the correct estimates.

It would appear that lag in sea response to changing winds is a larger source of error than sea–air temperature differences. For climatic averages lag errors will tend to cancel out, but are more of a disadvantage in making synoptic maps.

Effective Coefficients of Diffusivity for Atomic Bomb Clouds at One Thousand to Two Thousand Miles

EUGENE M. WILKINS

Abstract—Twelve selected radioactivity profiles through atomic bomb clouds, made one to two days after detonation, yield an average 'effective' coefficient of diffusivity, $K = 2.7 \times 10^8$ cm² sec⁻¹.

During the Nevada weapons tests carried out by the Atomic Energy Commission in January-February and October-November, 1951, aircraft flights were made through the nuclear clouds at various distances from the burst point to obtain radioactivity profiles. These measurements provide useful estimates of large-scale diffusion.

Machta and others [1957] have given the profiles for tests in January and February, together with explanations of sampling techniques and data limitations. The additional profiles used in this analysis are for clouds formed in the October-November tests, and these are sufficiently reproducible from the peak activities and σ values (standard deviations of radioactivity distribution) listed in Table 1.

The coefficients of lateral eddy diffusivity K in Table 1 were calculated for the radioactivity profiles that made a reasonable fit to a Gaussian curve, assuming that the classical Fickian law of diffusion is applicable. These are 'effective' coefficients, containing as they do the effects of wind shear and settling of particles. There was not a sufficient range of times and distances in the data to seek a trend of variation of K on these parameters. The average K for all 12 profiles may be adequate for estimate purposes within the range of circumstances in which they were determined, since the extremes differ from each other by less than a factor of six.

Richardson [1926] calculated $K = 5 \times 10^8$ cm² sec⁻¹ for the spreading of volcanic ash—an example of diffusion on a somewhat larger scale than the bomb clouds, but one in which K was comparable with the largest values listed in Table 1.

Two authors have computed K for this scale of diffusion using moisture variations along isentropic surfaces. *Grimminger* [1941] quotes a range of 3 to 87×10^8 cm² sec⁻¹ for mean monthly isentropic charts, and 6 to 390×10^8 cm² sec⁻¹ for daily charts. *Miller* [1948] quotes a range of 40 to 1000×10^8 cm² sec⁻¹ for daily charts. Possibly, the greater K values result from the use of profiles that were not good approximations to Gaussian curves (such profiles were rejected in the present analysis), but limitations in their data must also result from the inaccuracies of mixing ratio measurements.

Moore and others [1954] obtained $K = 4 \times 10^7$ cm² sec⁻¹ from the spread of constant-level balloons traveling about the same distances as did the bomb clouds. This is an order of magnitude less than the mean for the bomb clouds. Presumably, the three-dimensional nature of the debris, permitting vertical wind shears to act, contributes to this difference. Also, the initial separation of the balloons was quite small (of the order of yards) compared with the initial diameter of the bomb cloud (of the order of miles), and thus the eddies effecting balloon separation were restricted to the smaller sizes.

The distances given in the table are taken along the cloud path, determined from the meteorological trajectory nearest the sampling altitude. Trajectory and sampling altitudes were the same for all but five of the profiles, and for these the difference was only 1000 to 2000 ft.

In some cases, the straight line distance from the burst point was less than half of the path length, and one cloud made almost a complete circle around a stationary cyclone, not being intercepted by the sampling aircraft until the cloud had returned almost to the point of origin.

The clouds represented in the table cover a wide range of situations with regard to wind shear. Also, the surface burst was very much different from the others in that the inclusion of soil in the original fireball resulted in much larger and hence faster-settling radioactive particles. Nevertheless, the K values as computed for this cloud were very near the mean for the group.

It is interesting that one-third of all of the profiles taken in a complete traverse of the cloud gave a good fit to a Gaussian curve. An additional one-third could have been fitted crudely out to about 2σ. It was noted also that in several cases where the cloud became divided into two segments, giving two maxima in the radioactivity profile,

each segment had an approximately Gaussian profile out to distances represented by 2σ. The profiles used in Table 1 were very nearly Gaussian-shaped out to at least 3σ, at which point the radioactivity would be only one per cent of the peak.

Acknowledgment—The author is grateful to Lester Machta, K. M. Nagler, and R. J. List for advice in the preparation of this paper. The research was conducted and reported under the auspices of the U. S. Atomic Energy Commission.

Precipitation Scavenging from Atomic Bomb Clouds at Distances of One Thousand to Two Thousand Miles

EUGENE M. WILKINS

Abstract—A convenient rule of thumb is developed for estimating radioactive fallout in precipitation from nuclear clouds at distances of 1000–2000 miles for debris at and below the rain-forming layer. The rule states that rain falling through bomb cloud radioactivity greater than about 100 times background causes deposition activity in excess of 10,000 dpm/ft^2 day. A method is suggested for making a crude estimate of the areal distribution of radioactive rainout which should be applicable under circumstances similar to those in the examples analyzed.

Over the eastern United States, precipitation fell through clouds from the AEC atomic weapons tests of October-November, 1951. This afforded an opportunity to observe the effects of washout from bomb-debris clouds.

Aircraft flights through the clouds at various altitudes up to 25,000 ft msl, combined with the meteorological trajectory analyses, made it possible to delineate approximate areas covered by the clouds while over the eastern United States, and to estimate the regions swept by the clouds during the 24-hour sampling and precipitation collection periods.

Methods and limitations of flight monitoring have been discussed by *Machta* and others [1957], and *List* [1954] has given a comprehensive study of trajectories, fallout predictions and verifications, and discussion of techniques and limitations of ground monitoring in a report on a later weapons test. The main difference for the series discussed here is that collection trays were used in addition to gummed paper for the ground monitoring. Tray collections are expressed in units of disintegrations per minute per square foot per day (dpm/ft^2 day).

Areas swept by each of the debris clouds during a 24-hour period were drawn on a map for altitudes corresponding to 700, 500, and 400 mb. The cloud boundary was arbitrarily defined by a line corresponding to radioactivity approximately 100 times the background level. (The background level for the measurements reported here is of the order of one disintegration per minute per standard cubic meter of air, density = 1.293×10^{-3} gm cm^{-3}). These areas were then compared with maps showing the distribution of 24-hour deposition activity and concurrent precipitation. In this manner it was possible to see how precipitation and cloud position affected the deposition. This method of analysis was applied to three of the bomb clouds in the test series. The following facts were observed:

(1) In all cases where the debris cloud was present below the 500-mb level and precipitation occurred, the tray samples showed deposition of 10,000 dpm/ft^2 day or more.

(2) Presence of the nuclear cloud above the 500-mb level (but not below) and precipitation gave deposition amounts less than 10,000 dpm/ft^2 day, and in most cases the deposition was very small (less than 1,000 dpm/ft^2 day) regardless of the amount of precipitation.

(3) Presence of the cloud below the 500-mb level and no precipitation gave deposition amounts considerably less than 10,000 dpm/ft^2 day. The dry-weather deposition averaged about one-eighth as much as the washout deposition.

Figure 1 is an example for a bomb cloud that passed over the eastern United States on November 1, 1951. Similar results were obtained for the other clouds, but they did not cover so extensive an area. All of these clouds were from air bursts, the fireball not reaching the ground, so that the clouds contained practically no debris other than from the bomb itself.

For these tests, there were only five occurrences of deposition in excess of 100,000 dpm/ft^2 in a 24-hour period. In all five instances, the debris cloud was present (enclosed by the 100-times-background line, which corresponds to air concentration of about 3 dpm/ft^3) at the 700-mb level as well as at the 500-mb level, and 0.10 to 1.21 inches of rain fell during the collection period. The highest reading was 360,000 dpm/ft^2/day, occurring with 0.20 inch of precipitation.

Apparently, if the nuclear cloud is present at or below the rain-forming layer, only a small amount of precipitation is required to accomplish a relatively large amount of scavenging. Otherwise, it is difficult to explain how in some instances neighboring stations receive deposition on the

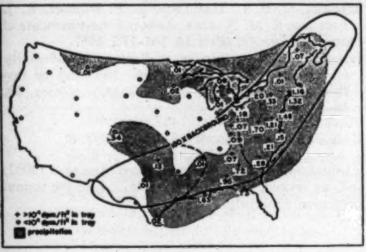

FIG. 1 – Area swept by the section of a nuclear cloud at the 500-mb level on November 1, 1951, in relation to distribution of radioactivity deposited in trays, and concurrent precipitation; the dashed line gives a rough estimate of the cloud position at the beginning and at the end of the sampling period; precipitation amounts are plotted below the station locations, pluses indicating deposition greater than 10,000 dpm/ft² and circles less

same order of magnitude despite a ten-fold greater rainfall at one of the stations.

It is most likely that all of the nuclear debris scavengeable by rain had been removed at the station receiving 1.21 inches of rainfall and a deposition of 260,000 dpm/ft². A station 300 miles away, but beneath the same nuclear cloud, received a deposition of 360,000 dpm/ft² with only 0.20 inch of precipitation. The bomb cloud had spread over so wide an area by this time that concentrations should have been fairly uniform, and the station receiving the lesser deposition was actually nearer the center of the cloud as it passed over. The implication is that the 0.20 inch of precipitation probably was as efficient in scavenging as the 1.21 inches.

This argument is further supported by the scavenging efficiencies computed in Table 1 for the two stations in question. These were made possible by virtue of the fact that the nuclear cloud concentrations (in the portion that subsequently passed into the rain area and over the stations) could be estimated from measurements made in flights through the cloud along the 84th meridian.

The assumption that scavenging occurred from 20,000 ft to the ground cannot be supported by any direct evidence, but it seems to be a reasonable one for these calculations. If it is assumed that a temperature of −12°C to −15°C is needed in the precipitation-forming layer, then the soundings indicate that the precipitation originated at a height of at least 18,000–21,000 ft. Elsewhere, it was observed that precipitation deposition was very light where the cloud was present at the 400-mb level, but not at the 500-mb level, and this suggests that essentially the scavenging occurred from a height between 18,000 and 24,000 ft.

TABLE 1 – *Calculations of scavengeable radioactivity from measurements taken in flights through the nuclear cloud along the 84th meridian on the morning of November 1, 1951*

Altitude	Cpm/30-min filter	Roughly equivalent concentration	Scavengeable activity (assuming an average] between levels)
Station receiving 0.20 inch of precipitation in nine hours			
ft			
20,000	1.5×10^5	47.2 dpm/ft³	24.5×10^4 dpm/ft²
10,000	5.6×10^3	1.8 dpm/ft³	0.9×10^4 dpm/ft²
Surface	(assumed negligible)		
Total scavengeable			2.54×10^5
Total observed			3.6×10^5
Scavenging efficiency			140 pct
Station receiving 1.21 inches of precipitation in nine hours			
20,000	1.9×10^5	59.7 dpm/ft³	30.2×10^4 dpm/ft²
10,000	2.2×10^3	0.7 dpm/ft³	0.35×10^4 dpm/ft²
Surface	(assumed negligible)		
Total scavengeable			3.055×10^5
Total observed			2.6×10^5
Scavenging efficiency			85 pct

These calculations are crude, but they do indicate that, for estimate purposes, it may be assumed that essentially complete scavenging will occur wherever 0.20 inch or more of precipitation falls through the nuclear cloud.

This study does not place an absolute upper limit for washout deposition at distances of one to two thousand miles; on the other hand, the opportunities for scavenging were certainly ideal. Presumably, greater deposition would occur in a situation where the rain-forming layer was higher, providing a greater depth in which scavenging could take place.

The analysis provides a 'rule of thumb' technique for making a crude prediction of precipitation deposition at distances of one to two thousand miles, provided that a forecast can be made of cloud position and precipitation at these distances. The author has shown [*Wilkins*, 1957] that a rough estimate of the lateral distribution of the cloud radioactivity (at various levels) can be obtained for these distances from the classical Fickian Law of diffusion and an 'effective' coefficient of lateral diffusivity, $K = 3 \times 10^8$ cm²/sec.

Acknowledgment—The author is grateful to Lester Machta, K. M. Nagler, and R. J. List for advice in the preparation of this paper. The data used were compiled by those mentioned above and by P. W. Allen, H. L. Hamilton, Jr., and L. F. Hubert of the U. S. Weather Bureau. The research was conducted and reported under the auspices of the U. S. Atomic Energy Commission.

A Max-Min Dew-Point Hygrometer*

C. B. TANNER AND V. E. SUOMI

Abstract—The lithium chloride Dewcel covered under Foxboro Company patent 2,359,278 has been used in conjunction with a max-min thermometer calibrated directly in degrees dew point to provide maximum and minimum and current dew points. The max-min feature of the hygrometer and the operation convenience make it a particularly suitable instrument for use at cooperative observer stations. A unique advantage of the lithium chloride Dewcel for a cooperating observer station is that the relative error of the measurement is the same at all dew points within the operating range.

First order weather stations collect a large number of hourly and daily meteorological measurements of interest to agriculturists and climatologists. However, the location of many stations on buildings and at airports often impairs the usefulness of the data for agricultural interpretation. In addition the small number of first-order stations limits the spacial sampling. Cooperating-observer stations are located to provide better data for agricultural purposes. In addition there is a far greater number of cooperating-observer stations than first-order stations. However, most cooperating observers collect only 24-hour rainfall and max-min air temperature data. Many other valuable measurements are not made because of the time required for the observer and the expensive equipment involved. Among these measurements are either dew point or relative humidity, net radiation, daytime and nighttime wind distance, and soil temperature. This article describes a simple instrument that provides maximum, minimum, and current dew points that is suitable for use in a cooperative observer station. The instrument is simple to operate and maintain and needs to be read only once a day.

Max-min dew-point hygrometer—The hygrometer assembly is shown in Figure 1. It consists of a Foxboro Dewcel element placed over the stem of a Weston max-min thermometer having a special scale graduated in dew point (°F or °C). A styrofoam shield is placed over the Dewcel element to protect the element from undue heat loss. A polyethylene skirt which drops over the upper end of the styrofoam shield protects the element from driving rain and snow. The hygrometer assembly is mounted in a stainless steel stand that holds the thermometer vertical, but permits the thermometer to be swung to a horizontal position for reading and setting the max-min indexes. A polyethylene cover (not shown) is placed over the thermometer head to shield it from precipitation. The unit is powered with a 25-volt a c, 50 watt transformer with a 50 or 60 watt 110-volt light bulb as ballast in the primary to prevent overloading. A double-wall hygrometer shield for use outside a conventional shelter is shown in Figure 2.

Tests of max-min dew-point hygrometer—The hygrometer was installed in the instrument shelter of the Madison weather station. It was read four times daily at 00 h 30 m, 06 h 30 m, 12 h 30 m, and 18 h 30 m. Psychrometer data were available for comparison at these times. Daily max-min dew points were read at 00 h 30 m and compared to the max-min values obtained by the psychrometer for the previous day. Data were accumulated over 40 days during April–May 1955; 100 days during late October 1955–January 1956; and 150 days during November 1956–April 1957. The data were divided into two classes: when ambient air temperature was above 32°F and below 32°F. The data are presented in Figures 3 and 4. It is to be emphasized that in Figure 3 much of the data nearest to the 1:1 correspondence line lies on previously plotted points.

The spread of data in Figure 3 is small and is accounted for by usual observer errors. Part of the difference is due to the fact that the psychrometer and the dew-point hygrometer have different time constants. Thus short-time fluctuations in dew point are included in the spread of data. The few points with large errors could have arisen from an even five- or ten-degree mistake in reading the hygrometer. Of particular interest in Figure 3 is the trend at low dew points for the psychrometer to read higher than the hygrometer. This trend is likely due to reading the wet bulb before it reached equilibrium.

In Figure 4 when dry-bulb temperatures were below freezing and the wet bulb would be frozen,

---

* Contribution from the Department of Soils, University of Wisconsin, Madison, Wisconsin.

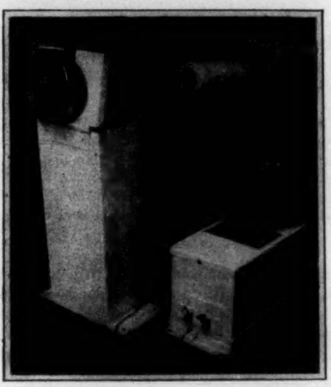

FIG. 1 – Max-min dew-point hygrometer and mounting for weather shelters

the spread of data is considerably greater than in Figure 3. Also evident is a trend for the psychrometer dew points to be lower than hygrometer dew points. This is probably a result of estimating too large a 'wet-bulb' depression. The wet-bulb and dry-bulb thermometers are graduated in even degrees and readings are estimated to 0.1°F. Since a depression is expected, observer bias results in estimating too large a depression. At very low temperatures a depression error of even 0.2°C can effect a large error in dew point. The same error would arise from a fixed error in the psychrometer thermometer calibration.

Characteristics of lithium chloride Dewcel—For each value of vapor pressure or dew-point temperature there exists only one temperature at which a saturated solution of LiCl will be in equilibrium, neither absorbing nor evaporating water. This temperature, conveniently called the LiCl dew point, is plotted against dew point over water in the lower boundary curve in Figure 5. The Foxboro Dewcel, reported by *Hickes* [1947], is a phase cell which is automatically maintained at the LiCl dew point of the ambient air. Thus a measurement of the Dewcel temperature provides the dew point or vapor pressure of the air in which the Dewcel is placed.

The operation and properties of the Dewcel have been discussed by *Hickes* [1947], *Conover* [1950], *Brasefield* [1954], and in detail by *Tanner* and *Suomi* [1956].

The *International Critical Tables* [1928, v. 3, p. 368] indicate that the relation of dew-point temperature to LiCl dew-point temperature is linear over four ranges, each with a different slope, according to the degree of salt hydration. *Brasefield* [1954] carefully calibrated a Dewcel with electronic dew-point equipment and found a linear relationship between dew point and the LiCl dew point over the dew point range −50 to 15°C and found that the data of the International Critical Tables agreed with his experimental data only at dew points above −5°C. *Tanner* and *Suomi* [1956] also found that experimental data and the data of the International Critical Tables agreed at dew points only above 0°C. Unpublished data by Tanner and data here reported confirm Brasefield's results at lower dew points. The FOXBORO COMPANY [1950] published data that indicate a linear relation between dew point and LiCl dew point (the Dewcel characteristic line) over the wide dew-point range of −50 to 45°C.

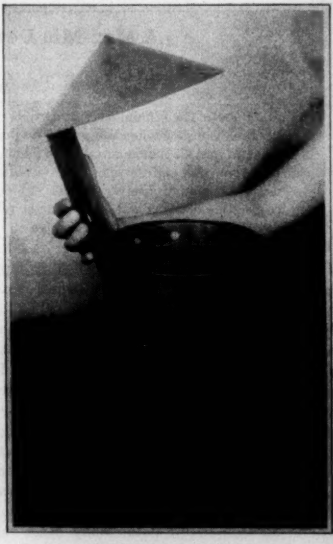

FIG. 2 – Dew-point hygrometer shield for use outside of shelters

Apparently the data of the International Critical Tables are a summary at early static-pressure measurements and are undoubtedly incorrect at dew points less than −10°C. The following equa-

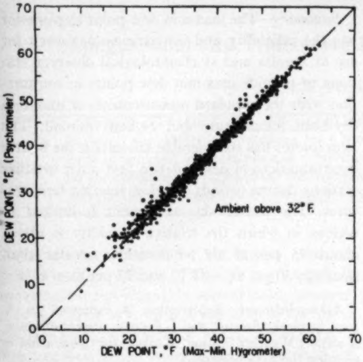

FIG. 3 - Comparison of dew-points from psychrometer and dew-point hygrometer (ambient air temperatures above 32°F)

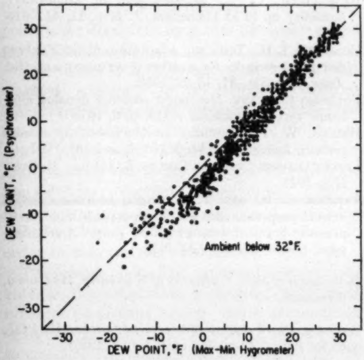

FIG. 4 - Comparison of dew points from psychrometer and dew-point hydrometer (ambient air temperature below 32°F)

tions relating dew point to LiCl dew point provide a good fit with experimental data in the dew-point range of −10 to 40°C.

$$(\text{Dew-point, °C}) = 0.6977\ (\text{LiCl dew point, °C}) - 24.33$$

$$(\text{Dew-point, °F}) = 0.6977\ (\text{LiCl dew point, °F}) - 34.1$$

These same expressions can be used to extrapolate the relation to lower dew points in accordance with Brasefield's findings.

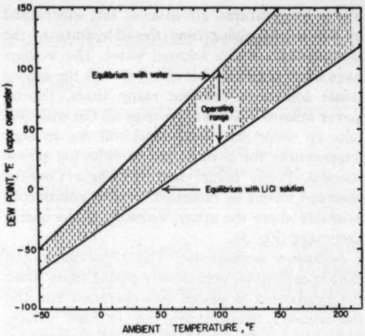

FIG. 5 - Max-min dew-point hygrometer operating range

Dewcel errors—The Dewcel is a heat-balance instrument. At its equilibrium temperature, the power input must equal the conductive, convective, and radiative heat losses. The Dewcel error is proportional to the power input. *Tanner* and *Suomi* [1956] found that the error in an unshielded Dewcel can be as much as 3°C in quiet warm air near saturation. Under these conditions the difference between the Dewcel temperature and ambient dry-bulb temperature is high, thus favoring high convective heat loss. When a Dewcel is exposed to the ventilation of the wind the error can be more serious. Thus heat losses must be minimized and kept as constant as possible by a suitable ventilation and radiation shield. The shield must allow the air sample to change slowly. If these precautions are not taken, large errors will result.

Tanner and *Suomi* [1956] found that the Dewcel reads higher than it should even when the ambient is close to, but not above, the LiCl dew-point. Consequently, the dew point as found from the Dewcel should be 2–3°C (4 to 6°F) above the lower operation boundary of Figure 5. Thus the Dewcel may not be suitable in some arid regions unless the air is refrigerated to the operating range. This is inconvenient.

The Dewcel can indicate dew points higher than those corresponding to saturation. In fogs the water droplets are carried into the Dewcel shield where they evaporate to raise the dew-point. *Conover* [1950] reported high dew point readings (10 to 80°F) when the Dewcel was operated at dew points below 0°F for some time and then rose to higher temperatures. He believes this was caused by the salt changing from the di-hydrate to the mono-hydrate which released water. The authors have never observed this effect, though the appropriate conditions obtained many times. During power failures of even a few minutes the wick will take up water and the Dewcel will rise to high temperatures for a short period following power renewal. Power failure and the effect Conover observed should be indicated by dew points considerably above the upper boundary of the operation range (Fig. 5).

Instrument maintenance—The thermometers can shift in calibration occasionally during times when the hygrometer is placed into operation and the thermometer temperatures rise to high values. This shift is a fixed calibration displacement of a small amount that does not affect the slope of the calibration curve and can be corrected by a suitable dew-point calibration at one and at most two dew points.

The element must be cleaned and recoated with LiCl once every three months. The hygrometer will read high and be sluggish in response if the coating is not renewed. The LiCl film is renewed by washing the old solution free with a jet of distilled water from a wash bottle. Excess water is blotted from the wick and a fresh solution is applied. When power is applied and the wick dries, a uniform white LiCl coating can be seen against the color of the wick. Excess LiCl, evidenced by salt blisters, will cause a sluggish response and may cause a high reading.

The styrofoam shield results in a 95-pct time constant of about 15 min. Thus the hygrometer is insensitive to high-frequency fluctuations in dew point. This is an advantage for most climatic observations.

Summary—The max-min dew-point hygrometer has the reliability and convenience necessary for use at regular and at climatological observer stations to provide max-min dew points in conjunction with the standard measurements of max-min dry-bulb temperature and 24-hour rainfall. The hygrometer has considerable advantage for hourly determinations of dew point in first-order weather stations during periods of below freezing temperatures. The use of the instrument is limited to regions in which the relative humidity is above about 15 pct at air temperatures greater than freezing; 30 pct at −25°F; and 75 pct at −45°F.

Acknowledgment—Appreciation is expressed to A. Joos, formerly director, and J. Rigney, present director, of airport Weather Station, Madison for cooperation in securing the data presented.

Longitudinal and Transverse Diffusion in Granular Deposits

G. DE JOSSELIN DE JONG

Abstract—The pore system of a packed bed is represented by a system of canals in order to permit probability computations for a foreign particle carried by the pore liquid movement to arrive at a certain place in a certain time. The computations lead to explicit values for the coefficient of longitudinal and transversal diffusion. A test device is described which permits the determination of the longitudinal diffusivity. The relationship between test result and theory is discussed.

Introduction—The flow of liquids through porous media is defined by Darcy's law when bulk movement is considered. In several cases, however, it is of interest to know how elements of volume or discrete particles carried by the liquid will travel. For instance, in the study of ground-water movement, radio active salts are injected into the soil. The salt will travel through different pores and after a given interval of time will arrive at different places, their distance from the starting point being dependent upon how tortuous was the path they followed.

This results in a dispersion of the injected salt which is additional to the molecular diffusion. This dispersion caused by the geometry of the pore canal system also has the character of a diffusion with a greater value in the mean direction of flow than perpendicular to this direction. Therefore the two different concepts longitudinal diffusion [*Klinkenberg* and *Sjenitzer*, 1956] and transverse diffusion [*Baron*, 1952] have been introduced in order to indicate this phenomenon.

The passage of the fluid between the grains consists of the summation of a great number of random phenomena, every single phenomenon being represented by the transition from one pore to another. The randomness is originated by the geometry of the pore canals around the grain, which is determined by the adjacent grains whose positions have a random character. This suggests the application of probability calculus in order to obtain an impression of the diffusion coefficients. Many workers have undertaken such probability computations. *Danckwerts* [1953], *Scheidegger* [1954], *Klinkenberg* and *Sjenitzer* [1956] obtain diffusion coefficients by application of probability, without defining the microstructural mechanism of the particle movement. Therefore their result contains a numerical constant, describing the granulometric properties of the porous medium which can only be determined by experiment (tests of *Kramers* and *Alberda* [1953] and *Klinkenberg* and *Sjenitzer* [1956]). Also *Day* [1956] describes such an approach, using the results of *Scheidegger* [1954]. The latter introduces an equal magnitude of transverse and longitudinal diffusion. Tests, however, pointed out that there is a marked difference (6 to 8 times).

In the determination of the diffusion coefficients presented here the starting point is a schematized pore canal system and the movement of the liquid through the canals is accounted for in detail.

Previously, others have applied mechanisms which introduced the grain dimensions (for transverse diffusion, *Baron* [1952]; for longitudinal diffusion, Kramers in a private communication, and *Rifai* and others [1957]). These mechanisms show a probability distribution of discontinuous character, the traveling particle being able to choose only between movements of +1, 0, or −1.

We preferred an approach where the probability distribution is continuous with respect to the direction of the path and proportional to the discharge of all the canals oriented in the direction considered. This approach enables derivation of an expression, which contains both transverse and longitudinal diffusity combined in one formula, and shows the observed difference of the diffusion coefficients in transverse and longitudinal direction.

This result was published by the author [*de Josselin de Jong*, 1956] in Dijon for brevity's sake without detailed mathematical explanation. Because of a regrettable computational mistake and some printing errors the formulas shown there are incorrect; so this article serves as a rectification and a justification of the mathematical treatment.

Notation—The following notation is used.

ℓ length of elementary canal

x, y, z, r coordinates of the exit of an elementary canal, when the entrance is placed in the origin

t residence time for particle in elementary canal

u residence time for elementary canal in principal direction of flow

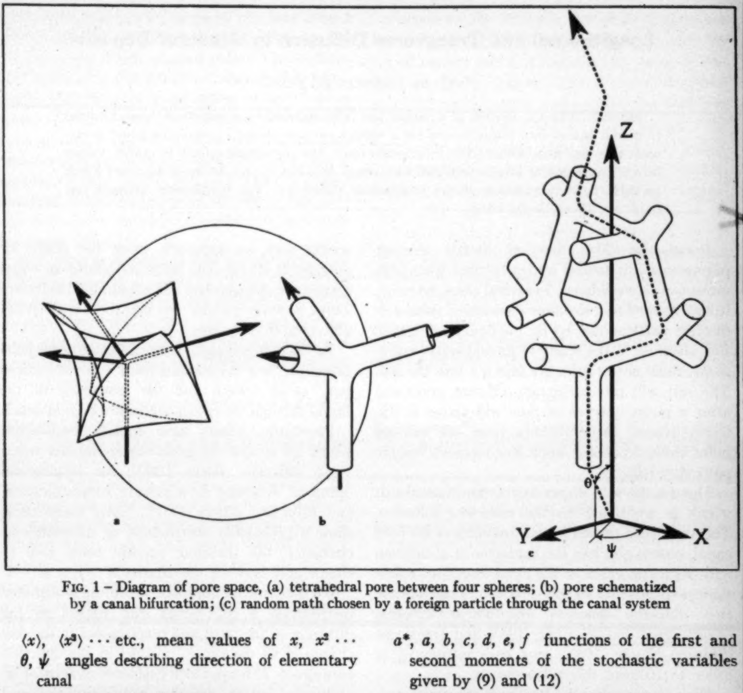

FIG. 1 – Diagram of pore space, (a) tetrahedral pore between four spheres; (b) pore schematized by a canal bifurcation; (c) random path chosen by a foreign particle through the canal system

$\langle x \rangle$, $\langle x^2 \rangle \cdots$ etc., mean values of x, $x^2 \cdots$

θ, ψ angles describing direction of elementary canal

$q_{\theta\psi}$, q_0, Q liquid discharge

v_0 mean velocity of liquid flow

$g_{\theta\psi}$, g_θ, g_ψ distribution functions for choice of paths

P probability function

X, Y, Z, R coordinates of arrival point of a particle, starting in the origin

T time of travel of the particle

N number of canals covered by the particle

X_0, Y_0, Z_0, R_0 coordinates of the maximum number of particles traveling during the time T_0

T_0 arrival time of the maximum number of particles covering a distance Z_0, R_0

N_0 number of canals covered by the maximum number of particles

σ_Z, σ_R, σ_T standard deviations of probability function with respect to Z, R, T

D_Z longitudinal diffusion coefficient

D_R transversal diffusion coefficient

ξ, η, ζ, τ integration variables

a^*, a, b, c, d, e, f functions of the first and second moments of the stochastic variables given by (9) and (12)

A, A', B, C functions given by (15)

λ function of distance Z_0 given by (13) and (23), represented graphically in Fig. 4

$\ln \gamma$ = Euler's constant ≈ 0.577

Schematization of canal system—The pores between grains of spherical form consist of nearly polyhedral cavities connected by triangular shaped canals (Fig. 1a). The resistance to the waterflow is principally determined by the narrow passages, these being oriented at random.

We will schematize this pore system by a network of canals linked together as indicated in Figure 1b. The orientation of the canals is at random, but uniformly distributed in all directions.

We will further suppose that the pressure gradient in each canal is proportional to cos θ, θ being the angle between its direction and the direction of principal flow, Z (Fig. 1c). If for a first approximation the lengths and the conductivity of all elementary canals are taken to be equal, the mean velocity of the liquid in each canal is proportional to $\cos \theta$.

The velocity of flow in the canal varies over its section, so that if a foreign particle moves at a velocity equal to that of the fluid in its immediate vicinity, its velocity will be depended on its radial distance from the center. Brownian motion, however, causes a radial diffusion in the canal [see *van Deemter* and others, 1955], so that if the canal section is small enough we may assume that the velocity of the foreign particle is equal to the mean velocity in the canal.

With these assumptions the residence time t_j in the canal j is given by

$$t_j = u/\cos \theta_j \tag{1}$$

where u is the shortest residence time possible, occurring in a canal oriented in the Z direction. If the length of an elementary canal is ℓ, the distance covered in the x, y, z directions by a canal is

$$x_j = \ell \sin \theta_j \cos \psi_j$$
$$y_j = \ell \sin \theta_j \sin \psi_j \qquad z_j = \ell \cos \theta_j \tag{2}$$

Choice of path—A foreign particle carried by the current through the canals has to choose a new direction of motion every time it arrives at a junction. We will assume that the choice of direction between θ, ψ and $\theta + d\theta, \psi + d\psi$ is distributed in proportion to the quantity of water flowing in these directions taken as a fraction of the total discharge of the canals.

This fraction is computed as follows: From a large number A of canals there are by virtue of the uniform distribution with respect to direction

$$A \sin \theta \, (2\pi)^{-1} \, d\theta \, d\psi \text{ canals}$$

oriented in a direction between θ, ψ and $\theta + d\theta$, $\psi + d\psi$. The discharge of these canals is $q_{\theta\psi} = Aq_0(2\pi)^{-1} \cos \theta \sin \theta \, d\theta \, d\psi$ where q_0 is the discharge of an elementary canal oriented in the Z direction. The total discharge of the A canals is

$$Q = (Aq_0/2\pi) \int_0^{2\pi} d\psi \int_0^{\pi/2} \sin \theta \cos \theta \, d\theta = \frac{1}{2} Aq_0$$

So the fraction of discharge in the $\theta \rightarrow \theta + d\theta$, $\psi \rightarrow \psi + d\psi$ direction is

$$g_{\theta\psi} d\theta \, d\psi = q_{\theta\psi}/Q = \pi^{-1} \cos \theta \sin \theta \, d\theta \, d\psi \tag{3}$$

The path followed by the particle is determined by the subsequent choices, each being distributed according to the distribution function $g_{\theta\psi}$.

In order to show the scattering effect let us consider how far a particle is deviated when it follows a canal in direction θ, ψ for a time Δt ($<u$). The velocity in this canal is $(\ell/u) \cos \theta$, so that the deviations Δz and Δr are

$$\Delta z = \Delta t \cdot (\ell/u) \cos^2 \theta = \tfrac{1}{2}(\Delta t \cdot \ell/u)(1 + \cos 2\theta)$$

$$\Delta r = \Delta t \cdot (\ell/u) \sin \theta \cos \theta = \tfrac{1}{2}(\Delta t \cdot \ell/u) \sin 2\theta$$

These deviations lie on a sphere with radius $\Delta t \cdot \ell/2u$ and center at $z = \Delta t \cdot \ell/2u$. The distribution function $g_{\theta\psi} = (2\pi)^{-1} \tfrac{1}{2} \sin 2\theta \, d(2\theta) \, d\psi$ also shows that the arrival points on the sphere are uniformly distributed over its surface. This scattering therefore bears a resemblance to Brownian motion super-imposed on a translation, and the problem has become one of random flight. However, there is a difference in that the residence time in the free paths for Brownian motion is independent of the orientation. For the problem considered here, the residence time is inversely proportional to $\cos \theta$, so that its value is infinite in the extreme case $\theta = \pi/2$.

For the determination of the diffusion coefficient we can, with some alterations, make use of the probability calculus developed for Brownian motion [*Chandrasekhar*, 1943, pp. 8–16].

Introduction of probability—When the particle has passed through a large number, N, of canals, it has arrived at a point X, Y, Z where

$$\left.\begin{aligned} X &= \sum x_j = \sum \ell \sin \theta_j \cos \psi_j \\ Y &= \sum y_j = \sum \ell \sin \theta_j \sin \psi_j \\ Z &= \sum z_j = \sum \ell \cos \theta_j \end{aligned}\right\} \tag{4}$$

The summation being from $j = 1$ to N. The time of travel is

$$T = \sum t_j = \sum u/\cos \theta_j \tag{5}$$

With the aid of Markoffs theorem [*Chandrasekhar*, 1943, p. 9] we can determine the probability $P_N(X, Y, Z, T) \, dX \cdot dY \cdot dZ \cdot dT$, that the particle after N passages has arrived in the volume between (X, Y, Z) and $(X + dX, Y + dY, Z + dZ)$ during the time interval T to $T + dT$, as

$$P_N(X, Y, Z, T) \, dX \, dY \, dZ \, dT$$
$$= \frac{dX \, dY \, dZ \, dT}{(2\pi)^4} \int_{-\infty}^{+\infty} d\xi \int_{-\infty}^{+\infty} d\eta \int_{-\infty}^{+\infty} d\zeta \int_{-\infty}^{+\infty} d\tau$$
$$\times \exp \{-i(\xi X + \eta Y + \zeta Z + \tau T)\} \times A_N \tag{6}$$

where

$$A_N = \left[\int_0^{\pi/2} d\theta \int_0^{2\pi} d\psi \, g_{\theta\psi} \right.$$
$$\left. \cdot \exp \{+i(\xi x_j + \eta y_j + \zeta z_j + \tau t_j)\} \right]^N$$

By introduction of T as the fourth component of the vector whose probability is determined, the dependence of the residence times on the stochastic variables is accounted for. The result P_N, however, is not yet sufficient because the particle may arrive at X, Y, Z in a time T in different ways with different numbers of passages N. For instance, the particle may choose a path which, being oriented in the z direction, brings it quickly very near to XYZ and then take a canal nearly perpendicular to Z with such a long residence time that the rest of T is consumed there. In that case the number of choices, is very small in comparison to the mean number of passages necessary. It is therefore necessary to integrate P_N over all possible values of N to obtain the required probability.

$$P(X, Y, Z, T) = \int_{N_1}^{N_2} P_N(X, Y, Z, T, N)\, dN \quad (7)$$

For points on the Z axis ($X = Y = 0$) the extreme values for N are $N_1 = Z/\ell$ and $N_2 = (ZT/u\ell)^{\frac{1}{2}}$.

Standard deviations—The probability distribution $P(X, Y, Z, T)$ for the arrival of one particle is a measure for the concentration distribution when a great number of particles is injected.

The dispersion may be described by diffusion coefficients which according to Einstein equa

$$D = \sigma^2/2T \quad (8)$$

where σ is the standard deviation of the probability distribution. As $P(X, Y, Z, T)$ is a function of X, Y, Z, and T we may derive for a given T, the place X, Y, Z where the probability is a maximum, and the standard deviation σ_X, σ_Y, σ_Z in the directions perpendicular and parallel to the principal stream around this maximum. But also we can take a fixed point in space and determine the standard deviation σ_T describing the changes of concentration in course of time at the moment when the maximum concentration passes.

In order to determine these standard deviations from the probability described by (6), several integrations have to be executed.

Integration of the expression for the probability—First the value of A_N has to be determined, which may be effected in a way similar to that shown by *Chandrasekhar* [1943]. We encounter here, however, the difficulty that t_j becomes infinite for $\theta = \pi/2$ according to (1).

We will not enter into the mathematical details, which can be obtained by request to the author, but infer, that to the neglect of small terms for $N \gg 1$, the following result is obtained.

$$A_N = \exp \{N[i\tau d + i\zeta e - (a^*\tau^2 + 2b\tau\zeta + c\zeta^2 + f\xi^2 + f\eta^2)]\} \quad (9)$$

with

$$a^* = [\ln (i/\gamma\tau u) - \tfrac{1}{2}]u^2$$
$$b = \tfrac{1}{2}[\langle tz\rangle - \langle t\rangle\langle z\rangle] = -u\ell/6$$
$$c = \tfrac{1}{2}[\langle z^2\rangle - \langle z\rangle^2] = +\ell^2/36$$
$$d = \langle t\rangle = 2u \qquad e = \langle z\rangle = 2\ell/3$$
$$\langle x\rangle = \langle y\rangle = \langle r\rangle = 0$$
$$f = \tfrac{1}{2}\langle x^2\rangle = \tfrac{1}{2}\langle y^2\rangle = \tfrac{1}{2}\langle r^2\rangle = \ell^2/8$$

where ⟨ ⟩ indicates the mean value.

Introduction of this value for A_N into (6) for P_N shows that next integrations versus τ, ζ, ξ, and η have to be executed. With respect to ζ, ξ and η this is readily performed by the use of the well known result

$$\int_{-\infty}^{+\infty} \exp (i\mu\alpha - \mu^2\beta^2)\, d\mu = \pi^{\frac{1}{2}} \beta^{-1} \exp (-\alpha^2/4\beta^2) \quad (10)$$

For the ξ, η part of the integral this gives, using polar coordinates, a result which yields the probability, that the particle should arrive in the ring between R and $R + dR$

$$(2\pi R\, dR/4\pi Nf) \;\exp\{-R^2/4Nf\} \quad (11)$$

From the τ, ζ part of the integral only the integration versus ζ may be treated according to (10) giving

$$(2\pi)^{-2}\, dT\, dZ(\pi/cN)^{\frac{1}{2}} \int_{-\infty}^{+\infty} d\tau \times \exp \{- i\tau[T - dN] + i(b/c)\tau[Z - eN] - ([Z - eN]^2/4cN) - N\tau^2[a^* - (b^2/c)]\}$$

The subsequent integration with respect to τ shows the difficulty that a^* is a function of τ. Here again we cannot extend upon the mathematical details, (which can be obtained by request) by which may be proved that a very good approximation is obtained by substitution of the constant a instead of a^* according to

$$a = (\lambda - \tfrac{1}{2} - \ln \gamma)u^2 \quad (12)$$

with λ the root of

$$N = \tfrac{1}{2}e^{2\lambda}/(\lambda - \tfrac{1}{2} - \ln \gamma) \quad (13)$$

The relationship between λ and N according to (13) is represented in Figure 2. Again the larger N, the better the approximation. With this substitution, the coefficient of τ^2 in the integrant is independent of τ, and (10) may be used. Then finally the following result is obtained for P_N.

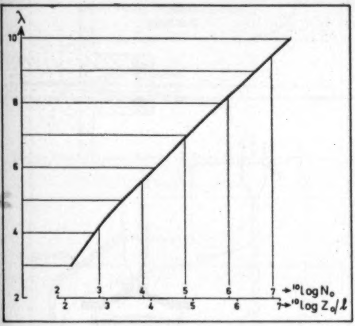

FIG. 2 – Graphical representation of Eq. 13 combined with Eq. 21; λ as a function of Z_0 the distance of the maximum concentration, and ℓ the elementary canal length

$$P_N(T, Z, R)\, dT\, dZ\, dR = (dT\, dZ\, R\, dR/8\pi N^2 f(ac - b^2)^{\frac{1}{2}})$$
$$\times \exp\{-(A + A')N^{-1} + B - CN\} \quad (14)$$

wherein

$$\left.\begin{aligned} A &= [cT^2 - 2bTZ + aZ^2]/4(ac - b^2) \\ B &= 2[cdT - b(eT + dZ) + aeZ]/4(ac - b^2) \\ C &= [cd^2 - 2b\, de + ae^2]/4(ac - b^2) \\ A' &= R^2/4f \end{aligned}\right\} \quad (15)$$

In order to obtain the diffusion coefficients as the final result of our considerations, the subsequent treatment of (14) for the probability P_N, that a particle after N choices arrives at a point Z, R in a time T, involves an integration with respect to N, and the determination of the standard deviations with respect to Z, R, or T. These operations become easy to perform if it is realized that according to the central-limit theorem the different probabilities involved will approach a normal law for $N \gg 1$. Therefore, if a result is obtained for the probability distribution of a variable μ given by

$$P(\mu)\, d\mu = \exp\{F(\mu)\}\, d\mu$$

we can replace the function F of μ in the exponent by

$$F(\mu) = F(\mu_0) + \tfrac{1}{2}(\mu - \mu_0)^2 F''(\mu_0) \quad (16)$$

where μ_0 is the value of μ for which $F(\mu)$ has its maximum. Because the distribution of $P(\mu)$ is approximately normal the higher order terms in the Taylor expansion of $F(\mu)$ may be neglected. From (16) it is obvious that the standard deviation of $P(\mu)$ approaches the value

$$\sigma_\mu = [-F''(\mu_0)]^{\frac{1}{2}} \quad (17)$$

The evaluation of an integral of the form

$$\int_{\mu_1}^{\mu_2} P(\mu)\, d\mu = \int_{\mu_1}^{\mu_2} \exp\{F(\mu)\}\, d\mu$$

can by virtue of the substitution (16) be approximated by

$$\int_{-\infty}^{+\infty} \exp\{F(\mu_0) - \tfrac{1}{2}[-F''(\mu_0)](\mu - \mu_0)^2\}\, d(\mu - \mu_0)$$
$$= [2\pi/ - F''(\mu_0)]^{\frac{1}{2}} \exp\{F(\mu_0)\} \quad (18)$$

The error introduced by the additional integrals over the intervals $-\infty \to \mu_1$ and $\mu_2 \to +\infty$ is negligible if the integrand in these intervals consists of an exponential of large negative value. In the case of the integration with respect to N, which has to be performed on (14) according to (7), the values of N_1, N_2, and $F(N)$ are such that in agreement with this condition the extension of the boundaries to $+\infty$ and $-\infty$ is permissible. Therefore the result of the integration versus N can be obtained by determining the value of N_0 for which $F(N)$ in (16) is a maximum and subsequently $F''(N_0)$. These determinations necessitate only differentiations on $F(N)$ being operations which are always feasible. Neglecting terms of small order, there results

$$N_0 = [(A + A')/C)^{\frac{1}{2}} \qquad \sigma = [N_0/C]^{\frac{1}{2}} \quad (19)$$

and the probability for the particle to arrive in time T at a point with coordinates Z, R is

$$P(T, Z, R)\, dT\, dZ\, dR = \frac{dT\, dZ\, R dR}{8f[\pi(ac - b^2)]^{\frac{1}{2}}} \left[\frac{C}{(A + A')^3}\right]^{\frac{1}{2}}$$
$$\times \exp\{B - 2[1 + C(A + A')]^{\frac{1}{2}}\} \quad (20)$$

wherein A, A', B, C are given by (15) and a, b, c, d, e, f by (9) and (12).

Character of the probability $P(T, Z, R)$—From (20) for the probability several conclusions may be drawn with respect to standard deviations. The expression is a function of T, Z and R because the factors A, A' and B contain them. The maximum of $P(T, Z, R)$ lies in T_0, Z_0, R_0 given by

$$T_0 = dZ_0/e = 3uZ_0/\ell \qquad R_0 = 0 \quad (21)$$

This means that the maximum concentration of an injected substance travels at a velocity v_0 equal to the mean velocity $\langle z\rangle/\langle t\rangle = \frac{1}{3}\ell/u$. That the maximum also follows the axis $R = 0$ is evident.

The standard deviations about the maximum may be derived with (17). We obtain then

$$\left.\begin{aligned}
\sigma_R &= [2Z_0f/e]^{\frac{1}{2}} = [Z_0\langle r^2\rangle/\langle z\rangle]^{\frac{1}{2}} = \ell[3Z_0/8\ell]^{\frac{1}{2}}\\
\sigma_T &= [2Z_0(cd^2 - 2bde + ae^2)/e^3]^{\frac{1}{2}}\\
&= [Z_0(\langle z^2\rangle\langle t\rangle^2 - 2\langle zt\rangle\langle z\rangle\langle t\rangle\\
&\quad + \tfrac{1}{2}(\lambda + \tfrac{3}{2} - \ln\gamma)u^2\langle z\rangle^3)/\langle z\rangle^3]^{\frac{1}{2}}\\
{}_T &= u[3Z_0(\lambda + \tfrac{3}{4} - \ln\gamma)/\ell]^{\frac{1}{2}}\\
\sigma_Z &= (e/d)\sigma_T = \tfrac{1}{3}\,\ell[3Z_0(\lambda + \tfrac{3}{4} - \ln\gamma)/\ell]^{\frac{1}{2}}
\end{aligned}\right\}\quad(22)$$

In these expressions Z_0 is the distance along the z axis, where the maximum is at the moment T_0. The maximum number of choices N_0 for the maximum at Z_0 is given according to (19) by

$$N_0 = Z_0/e = 3Z_0/2\ell \qquad (23)$$

The length of ℓ is given by the geometry of the pore canal system, while λ can be read from Figure 2 as a function of N_0 or computed by (13).

The standard deviation σ_T applies to the change of concentration registered at a point on the axis when the maximum passes by. The approximated value of σ_T as given in (22) is applicable for the case of a point injection as well as for the breakthrough curve of a plane front. Exact computation of these two different cases from (20) would yield a slightly different result.

The standard deviations σ_R and σ_Z represent the dispersion of a point injection in longitudinal and transverse directions at a certain moment. From these values the diffusion coefficients D_R and D_Z may be computed by (8) and give

$$\left.\begin{aligned}
D_R &= \sigma_R^2/2T_0 = 3\,v_0\ell/16\\
D_Z &= \sigma_Z^2/2T_0 = v_0\ell(\lambda + \tfrac{3}{4} - \ln\gamma)/6
\end{aligned}\right\}\quad(24)$$

From this result we deduce that the interrelation between these diffusion coefficients is

$$D_Z/D_R = 8(\lambda + \tfrac{3}{4} - \ln\gamma)/9 \qquad (25)$$

which according to (13) is dependent on the distance, since λ is a function of N_0 and $N_0 = 3\,Z_0/2\ell$. The order of magnitude of D_Z/D_R would be 6.5 for $N_0 = 10^5$.

In the foregoing computations ℓ the length of the elementary canals was invariable. The introduction of a statistically distributed canal length in the given analysis, entails no essential difficulties. We did not represent its influence because we assumed that for the example given by the experiment this influence was small in comparison to the scattering effect produced by the orientation of the canals.

Experiments—Several experiments have been run with the percolation apparatus represented diagrammatically in Figure 3. The cylinder (φ 6 cm, height 20 cm) was packed with glass spheres of 0.2 mm diameter (standard deviation 0.05 mm). The packing was carefully controlled to procure a uniform porosity of 38.5 volume pct.

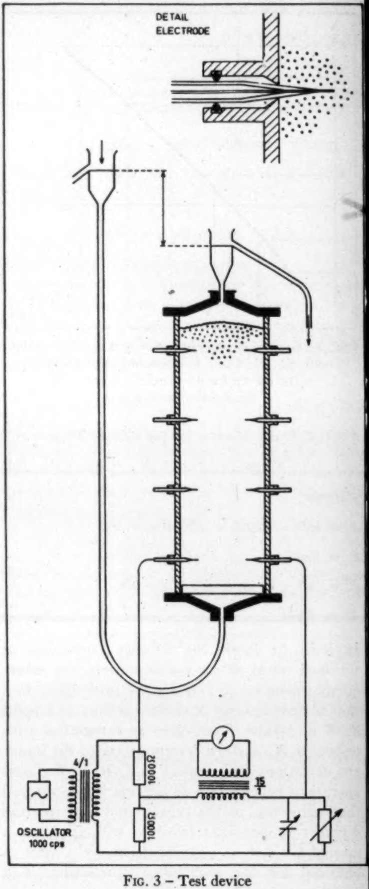

FIG. 3 – Test device

The system was saturated with distilled water with NaCl to a concentration of 0.02 normal. The liquid under the filter was replaced by water with a 1.0 normal NaCl concentration. Next the waterflow was started at a filter velocity upwards of

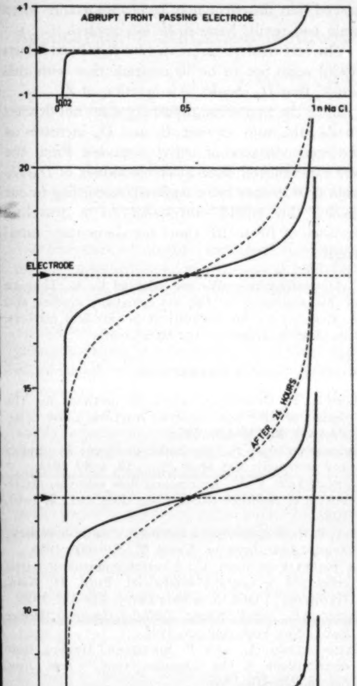

FIG. 4 – Salinity as registered by electrodes

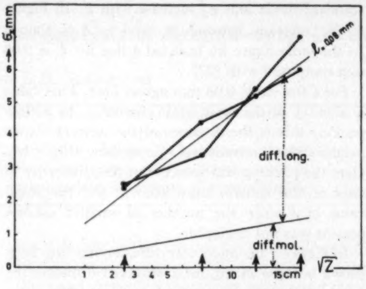

FIG. 5 – Observed standard deviations as related to theory

6 cm³/minute. The mean velocity through the pores $\langle z \rangle / \langle t \rangle$ was

$$(6/\tfrac{1}{4}\pi 6^2) \times (1/0.385) = 0.55 \text{ cm/min}$$

At different distances from the bottom (2.5, 7.5, 12.5, 17.5 cm) electrodes were inserted into the grain material, and permitted salinity measurements of the interstitial liquid. The electrodes consisted of a platinum wire ϕ 0.7 mm, length 3 mm and were covered with platinum-black. The electrical specific resistance of the material around these electrodes was determined with the Wheatestone bridge (1000 cps, 50 μA) represented diagrammatically in Figure 3. Calibration in different NaCl concentrations gave the relation between salinity and electric resistance in the circuit. Calibration in the liquid alone as well as after introduction of the grains gave values which correspond with theoretical computations based on potential distribution around ellipsoids and reduction of conductivity by the grain material. By measuring the resistivity variations with respect to time the break-through curve as the saline front passed by, could be determined.

In Figure 4 is given the salinity as registered by the electrodes at the moment that a particle traveling at the mean velocity would have arrived at the distance indicated by the abscissa. The error introduced by the finite dimension of the electrodes is shown by the curve at the top of Fig. 4 where, based on theoretical calculations of the potential distribution round ellipsoids, the apparent concentration variations measured by an electrode have been drawn for the passing of an abrupt front.

The observed curves show a distribution that is nearly normal. Their inclination increases with the distance from the bottom indicating that also the standard deviations σ_z increase with Z. In Figure 5 the relation between σ_z and $\sqrt{Z}$ is shown. In the same figure we inserted a line for $\ell = 0.08$ mm computed with (22).

For ℓ the value 0.08 mm agrees best. This value is about ⅓ of the main grain diameter. In a close packing this is the distance of the centers of two neighbouring tetrahedral pores (see Fig. 1a). Here the packing was looser, but the difference in sizes of the spheres may account for the small value of ℓ since the number of smaller spheres present was not negligible.

In Figure 5 the molecular diffusion has also been shown because in the total observed diffusion the effect of Brownian motion is present. Molecular diffusion was determined in the percolation apparatus as follows.

The percolation test was executed as above for the front passing the two lower electrodes. Then the liquid flow was stopped during 24 hours and started again in order to let the front pass the two upper electrodes. The additional inclination of the break-through curves correspond to an acceptable diffusion coefficient of

$$D_m = 0.7 \times 10^{-5} \text{ cm}^2/\text{sec}.$$

The normal runs lasted about 30 minutes, so the influence of molecular diffusion was not sufficient to affect the interpretation of the test results (see Fig. 5).

Conclusions—The introduction of a continuous probability distribution for the random choice of travel direction at a bifurcation in the pore canal system permits the computation of longitudinal and transversal diffusion from a formula which contains both together as a probability expression (20). Both diffusion coefficients are proportional to the mean velocity, as has previously been found by several other workers in this field. Further they are proportional to ℓ which is of the order of the grain size, but depends on the grain-size distributions and packing. In the glass beads packing investigated ℓ amounted to about ⅓ of the mean diameter of the grains.

The longitudinal diffusion coefficient moreover depends on the distance Z_0, which has been covered by the particle traveling at the mean velocity. This dependence is nearly proportional to $\ln \sqrt{Z_0}$. In experiments, where Z_0 varies over a small range this dependence will remain unobserved, but the effect may be of importance when scale test results have to be interpreted.

The test results represented by *Rifai* and others [1956] seem not to be in contradiction with this result, that D_Z should be a function of Z_0.

Since the transverse diffusivity does not depend on Z_0, the ratio between D_Z and D_R increases as the mean distance of travel increases. From the few experimental data available values of D_Z/D_R from 6 to 10 have been reported. According to our theory this would correspond to a traveling distance of 10^5 to 10^8 times the elementary canal length.

Acknowledgments—We are indebted to R. Timman for his assistance in the mathematical studies and H. Kramers for his suggestions in physical matters. Miss Hoving carried out the experiments.

Application of Statistical Methods to the Analysis of Ground-water Levels

IRWIN REMSON AND J. R. RANDOLPH

Abstract—Valuable hydrologic information can be obtained from statistical analysis of water-level trends. The time-series and the functional-equation approaches are applied to New Jersey well records representing different hydrologic conditions. The results are valuable as concise summaries of the records, for extrapolating observed data, for interpolating between measurements, and for estimating hydrologic factors such as coefficients of transmissibility and storage, evapotranspiration, and ground-water discharge.

Introduction—Valuable hydrologic information can be obtained from the statistical analysis of ground-water level trends. Such analysis can separate and define the factors responsible for the water-level movements. It can be used to interpolate between measurements or predict future water levels under given conditions. Numerical expressions can be derived that concisely summarize the record. Finally, this approach helps to clarify important hydrologic factors such as coefficients of transmissibility and storage, evapotranspiration, and ground-water discharge.

Two types of statistical analysis are applied in this paper to records of water-levels. One method analyzes them as time series and separated the secular (long-term), annual, cyclical, and irregular trends. Its primary purpose "is to discover and measure any irregularities which characterize the movement of the data through time" [*Neiswanger*, 1948, p. 475]. The other method derives functional relationships between water levels and other hydrologic factors. Some data are suited to the time-series approach, some to the functional approach, and some to a combination of both.

Water-level records from three different areas in New Jersey are analyzed to show the applicability of the methods to different hydrologic conditions. Water-level trends in the well at Longport are affected most by artificial ground-water withdrawals. Data from a water-spreading area near Seabrook illustrate the effects of artificial ground-water recharge. Water-level trends in the Hulsart well near Old Bridge reflect climatic and other natural conditions. For the Seabrook analysis, measurements from a dense network of observation wells were used, whereas for the Hulsart and Longport analysis, measurements from single wells were used.

Analysis of water-level trends in the well at Longport, N. J.—The Longport (14th Avenue) well, located along the coast of New Jersey, reflects water levels in the aquifer known locally as the 800-foot sand. Longport, Margate City, Ventnor City, and Atlantic City to the north, and Ocean City to the south, draw substantial quantities of water from this confined aquifer [*Thompson*, 1928; *Barksdale*, *Sundstrom* and *Brunstein*, 1936].

Figure 1 and column 2 in Table 1 show the monthly median water levels in the Longport well, below an arbitrarily chosen datum, for the period from 1925, the first year of complete record, through 1952. The datum is the median water-level altitude of January 1925, 15.0 ft below mean sea level. The seasonal fluctuations result largely from the seasonal changes in pumping rates. The general water-level decline from 1925 until 1929, the slight recovery beginning with 1930, and the marked decline since 1944 correlate with changes in rates of pumping from the aquifer.

Figure 1 shows clearly defined secular (long-term) and annual (seasonal) variations. Therefore, it is well suited to the time-series type of analysis. Of the several time-series methods available, the ratio-to-trend method [*Arkin* and *Colton*, 1950, pp. 67–75] was used to separate and clarify the most prominent individual trends in the record.

The first step in the application of the ratio-to-trend method is the determination of the long-term or secular behavior of the data. Because of the distribution of the data, this was done by fitting the following to the hydrograph

$$s = K_1 + K_2 \log_e t \qquad (1)$$

where s = the drawdown of the water level in the Longport well below the datum, ft

t = the elapsed time since datum period of January 1925, days

K_1 and K_2 = constants

Eq. (1) was fitted to the Longport data by

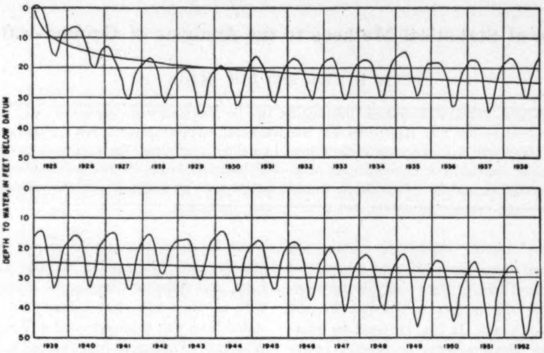

FIG. 1 – Hydrograph of the 14th Avenue well, Longport, N. J., with the long-term trend line superposed

applying the principle of least squares. The sum of the squares of the deviations of the observed values about the trend line computed by this method is a minimum. The least-squares line was determined from the 'normal' forms of (1) [*Arkin* and *Colton*, 1950, pp. 210–211].

$$\sum s = NK_1 + K_2 \sum \log_e t$$

$$\sum (s \log_e t) = K_1 \sum \log_e t + K_2 \sum (\log_e t)^2 \quad (2)$$

where N is the number of items in the set of data to which the equations are applied.

Using yearly mean values of drawdown s and time t for 1925 through 1952, the solution of the normal equations is

$$K_1 = -14.68 \text{ and } K_2 = 4.65$$

Substituting these values in (1), the long-term trend equation for the Longport well becomes

$$s = -14.68 + 4.65 \log_e t \quad (3)$$

A trend line based on (3) is plotted on the Longport hydrograph, Figure 1. It shows the trend values of s, the computed position of the water table below the datum. Each trend value of s, listed in column 4 of Table 1, corresponds to an actual median water-level position below the datum (Table 1, column 2). The following steps analyze the differences between the actual and trend values of s.

In the second step of the analysis, the ratio of each observed value of s to its respective computed trend value was listed in column 5 of Table 1. The departures of the ratios from unity measure the deviations of the observed water levels from the computed long-term trend values. Column 5 shows that the July 1925 drawdown, for example, was 23 pct greater than its respective trend value, and the December 1925 drawdown was 37 pct less than its respective trend value.

In the third step, the ratios were averaged by months after extreme values were eliminated by means of a multiple-frequency table [*Arkin* and *Colton*, 1950, p. 71]. The resulting monthly average indices of variation (seasonal indices), column 6, Table 1, show the typical position of the water level for each month relative to the trend position. For example, January drawdowns average 18 pct less than the trend values, and July drawdowns average 24 pct greater than the trend values.

In the fourth step, the respective monthly indices of variation were subtracted from the individual monthly ratios in column 5. This removed the average monthly variations from the data. The resulting values in column 7 represent the cyclical and irregular deviations remaining in the data after the secular and seasonal trends have been removed.

In the final step of the analysis, the data were smoothed by means of a 12-month centered moving average [*Arkin* and *Colton*, 1950, pp. 46–49]. This removed the irregular variations and isolated the cyclical variations, listed in column 8 of Table 1. Since 1947, a cycle has been in progress during which water-level drawdowns have been greater than the combined trend and annual values. Table 1 shows that the cyclical water-level drawdowns

were 24 pct of the trend values in the first part of 1952.

In summary, the time-series analysis of the Longport hydrograph yielded: (1) The trend equation: $s = -14.68 + 4.65 \log_e t$; (2) monthly indices (Table 1, column 6); and (3) cyclical and irregular deviations for 1952 (Table 1, column 7).

The deviations of the actual monthly indices from the average monthly indices were larger during the summer of 1952 than during the rest of the year. Such unanalyzed deviations are included in the cyclical and irregular deviations. Therefore, the cyclical and irregular deviations rather than the cyclical deviations alone were included in the summary of Longport well data shown above.

The results of the time-series analysis were used to predict water-level drawdowns for 1953, as shown in Table 2. It was assumed that the secular and annual (seasonal) trends would continue, that the irregular deviations for 1953 would be the same as those computed for 1952, and that the cyclical deviations would increase at the rate of one per cent of the trend values every five months. Eq. 3 was used to determine the secular-trend values in column 3 of Table 2. The 1952 cyclical and irregular deviations, having been increased at the rate of one per cent every five months (col. 5), were added to the monthly indices (col. 4) to give total indices (col. 6). The secular trend values were finally multiplied by the total indices to give the predicted water levels below datum (col. 7). Comparison with the observed drawdowns in column 8 shows that no large changes in the causative factors occurred in 1953.

Further analysis of the Longport data is facilitated if it is assumed as an approximation that the secular trend is determined by the ground-water withdrawls [*Barksdale, Sundstrom*, and *Brunstein*, 1936, pp. 97–99]. The following modified form [*Jacob*, 1946, pp. 629–646] of the *Theis* [1935, pp. 519–524] nonequilibrium equation is then applicable:

$$s = \frac{114.6Q}{T}\left(-0.577216 - \log_e \frac{1.87r^2S}{T} + \log_e t\right) \quad (4)$$

where T is the coefficient of transmissibility expressed as the rate of flow of water, in gallons per day, through a vertical strip of aquifer, one foot wide and extending the full saturated height, under a hydraulic gradient of 100 pct at the prevailing temperature of the water, S is the coefficient of storage of the aquifer or the volume of water it releases from or takes into storage per unit surface area of the aquifer per unit change in the component of head normal to that surface, Q is the pumping rate, in gallons per minute, and r is the distance from the observation well to the center of pumping, in feet.

Comparing (4) with (1)

$$K_1 = \frac{114.6Q}{T}\left(-0.577216 - \log_e \frac{1.87r^2S}{T}\right)$$

and

$$K_2 = \frac{114.6Q}{T} \quad (5)$$

For (5) to be strictly applicable, Q must be a constant, whereas the pumping rate from the Atlantic City 800-foot sand varies with time. However, average values of K_1 and K_2 were derived from the solution of (2), and average pumping rates can be used to approximate Q. The average pumping rate during the period 1925–1952, inclusive, was 5800 gallons per minute. The average pumping rate in 1917–1925 was estimated from *Barksdale, Sundstrom*, and *Brunstein* [1936, p. 13] as 3750 gallons per minute. Therefore, Q, the pumping-rate change causing the drawdowns s, was taken as 2050 gallons per minute and was assumed to occur suddenly. The distance from the observation well to the center of pumping r was approximately 29,000 ft from a weighted average of the distances to the individual wells.

The solutions of (4) and (5) gave T = 50,000

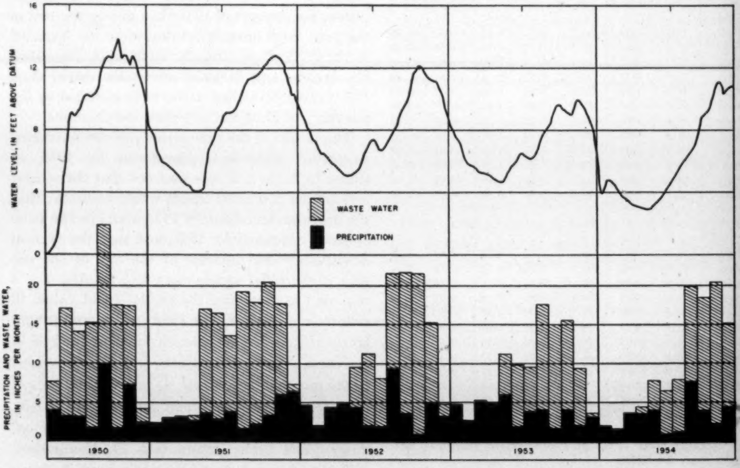

FIG. 2 – Composite hydrograph of wells in the Seabrook spreading area compared with precipitation and waste water

gallons per day per foot and $S = 0.0003$. This agrees with the results of a pumping test at Pleasantville, where T was about 60,000 gallons per day per foot and S was about 0.0003.

Analysis of water-level trends in the Seabrook spreading area—On a 390-acre woodland near Seabrook, N. J., 700 to 1200 million gallons of waste water are spread annually [*Remson*, 1954, pp. 4–15]. The infiltration capacity of the soil is large, and most of the applied water moves downward to the zone of saturation. The aquifer, thus recharged, is drained by streams along the margins of the area.

Figure 2 shows arithmetic averages of water-level altitudes above an assumed datum (average water-level of May 1, 1950) in 29 wells, precipitation, and amounts of applied waste water. Because the spreading pattern and water-level trends changed from year to year, the functional approach is preferable to the time-series approach for this analysis.

Consider a unit vertical prism of aquifer near one of the observation wells. The water balance for such a prism may be expressed as

$$q = w - S(\Delta h/\Delta t) \tag{6}$$

where $q =$ the difference between the rates of ground-water flow into and out of the unit prism
$w =$ the rate of recharge to the prism from above the water table
$S =$ the coefficent of storage of the aquifer
$\Delta h/\Delta t =$ the time rate of change in the altitude of the water table in the unit prism

Assume as approximations, that flow from the ground-water divide to the streams is linear and that S, w, and $\Delta h/\Delta t$ are constant along the entire flow line. Then, q is constant over the flow line, and

$$q_t = q(L - x) \tag{7}$$

where $q_t =$ the total average rate of ground-water discharge through the unit prism
$x =$ the distance from the external hydraulic control, the stream draining the spreading area, to the center of the unit prism
$L =$ the total distance from the stream to the ground-water divide

If the ground-water flow follows Darcy's law the total average discharge through the unit prism may be expressed as

$$q_t = T(dh/dx) \tag{8}$$

where $T =$ the coefficient of transmissibility
$dh/dx =$ the hydraulic gradient or the space rate of change of the altitude of the water table

If it is assumed as an approximation that T is a constant, (7) and (8) may be equated, rearranged, and integrated along the flow line between the stream and the unit prism.

$$\int_0^x (L - x)\, dx = (T/q) \int_H^h dh$$

$$q = \frac{T(h - H)}{Lx - x^2/2} \tag{9}$$

where $H =$ the altitude of the water level in the stream, coinciding with the water-table altitude at the stream position
$h =$ the altitude of the water table in the unit prism, at a distance x from the stream

If a more rigorous approach is required, the product of permeability and saturated thickness can be used instead of T.

From (6) and (9)

$$w = S(\Delta h/\Delta t) + \frac{T(h - H)}{Lx - x^2/2} \tag{10}$$

For a single observation well, x and L are constants. Two constants, A and B, therefore may be chosen so that

$$A = \frac{2T}{2Lx - x^2} \text{ and } B = AH \tag{11}$$

Then

$$w = S(\Delta h/\Delta t) + Ah - B \tag{12}$$

can be used as the functional equation to represent the hydrologic changes in the vicinity of any observation well. The time lags between the different factors in (12) could be neglected at Seabrook because of the large water applications and the use of monthly data.

The rate of recharge to the water table w may be evaluated from

$$w = p + b - g - e - \Delta v/\Delta t \tag{13}$$

where p = the rate of precipitation
b = the rate of waste-water spreading
g = the rate of direct runoff to the streams
e = the rate of evapotranspiration
$\Delta v/\Delta t$ = the rate of change of soil-moisture storage, positive for an increase in soil-moisture storage and negative for a decrease in soil-moisture storage

Much of the spreading area was constantly wet because of the water spreading. Therefore, evapotranspiration was evaluated by using the *Thornthwaite* [1948, pp. 54–94] formula for potential evapotranspiration.

Because of the large quantities of water entering the spreading area, the soil-moisture reservoir remained essentially full, and $\Delta v/\Delta t$ was zero for all practical purposes. Furthermore, there was no direct runoff because of the large infiltration capacity. Therefore, (13) becomes

$$w = p + b - e \tag{14}$$

When using (13) and (14), it is assumed that no ground-water is lost by evapotranspiration. Then, the rate of ground-water recharge per unit area w is always positive or zero.

Eq. (12) modified by (14) applies to a single unit vertical prism of the aquifer in the vicinity of one observation well. Assuming that the ground-water activity is adequately sampled by the observation-well network and that S and T are constants, the separate equations for the prisms and observation wells can be totaled to give summation forms. However, the work of computation can be greatly reduced by using average values of x, L, H, and $\Delta h/\Delta t$ in the equations as an approximation. This is equivalent to replacing the 29 observation wells by a single average well.

The normal forms of (12) are readily derived by again applying the principle of least squares. They are

$$\begin{aligned} \Sigma w &= -NB + S\,\Sigma \Delta h/\Delta t + A\Sigma h \\ \Sigma(w\Delta h/\Delta t) &= -B\,\Sigma \Delta h/\Delta t + S\Sigma\,(\Delta h/\Delta t)^2 \\ &\qquad + A\Sigma(h\Delta h/\Delta t) \\ \Sigma(wh) &= -B\Sigma h + S\Sigma(h\Delta h/\Delta t) + A\Sigma\,(h)^2 \end{aligned} \tag{15}$$

where N is the number of items in the set of data to which the equations are being applied. Solving (15) for the 55 months of record, the functional equation for the spreading area was found to be

$$w = 0.17(\Delta h/\Delta t) + 1.65\,h - 4.60 \tag{16}$$

or

$$\Delta h/\Delta t = 27.06 + 5.82\,w - 9.71\,h \tag{17}$$

The standard errors are 0.69 for B, 0.04 for S, and 0.25 for A.

The coefficient of correlation between w and h is 0.72. The coefficient of correlation between $\Delta h/\Delta t$ and h is -0.10, indicating poor correlation as was to be expected. Finally, the coefficient of correlation between w and $\Delta h/\Delta t$ is 0.56. This relatively low value resulted from the uneven distribution of the spreading water. When spreading occurred in the vicinity of the wells, the measured water levels rose more than when equal amounts of water were spread between them. Large water applications near the streams affected composite water levels less than similar applications near the center of the area. Therefore, the assumption that w was uniform over the spreading area was not strictly true, and some errors were introduced.

Eq. (12) and (14) were used to predict rates of change of the composite water level $\Delta h/\Delta t$ for December 1954. For this period, b was zero, p was 3.87 inches per month, e was 0.52 inch per month, and h was estimated as 7.83 ft on the basis of previous water levels. Therefore, w was found to be 3.35 inches per month, and $\Delta h/\Delta t$ was computed as -40.9 inches per month. The actual value of $\Delta h/\Delta t$ was -36.8 inches per month. This is satisfactory agreement considering the approximations used in the derivation of the functional equation.

Analysis of water-level trends in the Hulsart well—The Hulsart well is near Old Bridge, N. J. The infiltration capacity in this area is large, and there is no nearby artificial recharge or artificial discharge of ground water. Water levels are controlled by natural hydrologic factors: precipitation, evapotranspiration, and natural ground-water discharge.

Figure 3 shows water levels in the Hulsart well. No secular trend is apparent in this hydrograph. The annual (seasonal) trend reflects the seasonal nature of the evapotranspiration. In general, most summer rainfall is used to replace depleted soil moisture, and little ground-water recharge occurs. However, an exceptionally heavy rain can restore the soil-moisture storage even in midsummer, and also recharge the gound-water reservoir causing departures from the seasonal trend.

The Hulsart water-level record is not suitable for time-series analysis because of the absence of clearly defined trends. From the known hydrology,

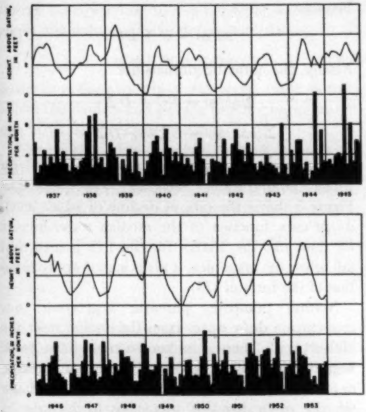

FIG. 3 – Hydrograph of the Hulsart well and precipitation

the functional type of approach is more applicable to this area.

Assume that flow from the ground-water divide to the stream is linear and follows Darcy's law. In addition, assume that S, $\Delta h/\Delta t$, w, and T are constant along the entire flow line through the Hulsart well. The functional equation (12), modified by (13), is then applicable. Because no data were used for times when the daily rainfall exceeded two inches, it can be assumed that the infiltration capacity of the sandy soil was never exceeded and that there was no direct runoff. Therefore, (13) becomes

$$w = p - e - \Delta v/\Delta t \tag{18}$$

Ground-water losses to phreatophytes and direct evaporation occur only in the vicinity of the stream, 500 ft from the Hulsart well. They do not affect the analysis because water lost in this area otherwise would have been discharged to the stream. Therefore, the evapotranspiration e in the vicinity of the Hulsart well is derived only from precipitation and soil moisture, and ground-water recharge w is positive or zero.

The distribution of rainfall and evapotranspiration within a given month is important in determining the amount of ground-water recharge, and monthly summations cannot be used for this computation. If soil moisture is to be taken into account, it is necessary to derive a daily or instantaneous water budget for the soil that involves w, p, and e. Because of the difficulty of this task, a different approach was used in analyzing the Hulsart records. This involved a separate analysis of data for periods of small change in soil-moisture storage and for periods of negligible ground-water recharge.

The average January evapotranspiration, based on the Thornthwaite equation, was 0.18 inch for the period of ground-water record. January precipitation averaged 3.87 inches for the same period. Therefore, practically every rainfall exceeded the soil-moisture deficiency and recharged the water table. Under such conditions, (18) can be evaluated on a monthly basis, $\Delta v/\Delta t$ being taken as zero. Thus, for the January data, (6) becomes

$$q = w - S(\Delta h/\Delta t) \tag{19}$$

where

$$w = p - e$$

Figure 4 shows the January relations between the water-level changes in the Hulsart well and precipitation minus evapotranspiration at the Runyon, N. J., weather station [U. S. Weather Bureau, 1937–1953]. The two points that fall above the main plot were disregarded because they reflect heavy rainfalls that took place at the ends of the preceding Decembers.

Ground-water discharge q depends upon the altitude of the water table h and tends to lower water levels. Because January is generally a time of rapidly rising levels, the relatively small tendency for ground-water discharge to lower the levels, and the effects of changing ground-water

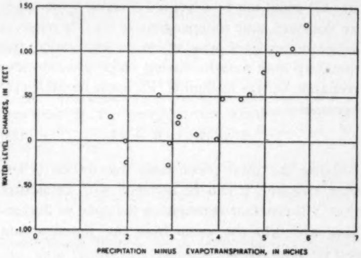

FIG. 4 – Relation between the January water-level changes in the Hulsart well and January precipitation minus evapotranspiration

discharge, are obscured. A plot of the rate of water-level change $\Delta h/\Delta t$ versus position of the water table h consequently showed no clear relationship between these two factors. Therefore, as an approximation, the ground-water discharge q was taken as a constant Q' for January regardless of the height of the water table, and (19) becomes

$$w = S(\Delta h/\Delta t) + Q' \tag{20}$$

For months during which there were only small water-level rises or there were declines, the effects of h and q did become significant. This explains the increased scattering of points in Figure 4 at low values of $\Delta h/\Delta t$. However, only negligible errors are likely to result from this scattering and the assumption of constant January ground-water discharge.

Eq. (20) and Figure 4 indicate a straight line with a slope equal to S and a w intercept equal to Q'. The normal equations for (20) are [*Arkin* and *Colton*, 1950, pp. 210–211]

$$\begin{aligned} \Sigma(w\Delta h/\Delta t) &= Q'\,\Sigma(\Delta h/\Delta t) + S\,\Sigma(\Delta h/\Delta t)^2 \\ \Sigma w &= NQ' + S(\Delta h/\Delta t) \end{aligned} \tag{21}$$

The solution of the normal equations gave a coefficient of storage S equal to 0.19 and a rate of ground-water discharge Q' equal to 3.04 inches per month for January. The standard error of estimate of w was 0.47, and the coefficient of correlation was 0.92. Therefore, the equation describing the January data can be written as

$$w = 0.19(\Delta h/\Delta t) + 3.04 \tag{22}$$

where

$$w = p - e$$

The computed rate of ground-water discharge in (22) could not be accepted because q was taken as constant and independent of h. Therefore, a separate analysis was made to determine this quantity from months during which ground-water recharge, w, was negligible. For such months, (12) becomes

$$S(\Delta h/\Delta t) = B - Ah \tag{23}$$

Because the total water-table fluctuation is less than five feet, it can be assumed with confidence that S is constant throughout the zone of fluctuation, and 0.19 the value from the January data can be used. Then

$$0.19(\Delta h/\Delta t) = B - Ah \tag{24}$$

Let $C = B/0.19$ and $D = -A/0.19$, and (24) becomes

$$\Delta h/\Delta t = C + Dh \tag{25}$$

Finally, the normal equations are

$$\begin{aligned} \Sigma\Delta h/\Delta t &= NC + D\,\Sigma h \\ \Sigma(h\Delta h/\Delta t) &= C\,\Sigma h + D\,\Sigma(h)^2 \end{aligned} \tag{26}$$

Data were examined, and months selected for which ground-water recharge was negligible. Figure 5 shows the rate of decline of water levels $\Delta h/\Delta t$ as a function of the median water-level h for these months. Except for the five points that fall below the main plot, it gives a good approximation of the form of (25).

Neither pumping, phreatic vegetation, nor evaporation draw water from the aquifer near the Hulsart well. There is no known cause for w to be negative, for ground-water declines to be excessive, or for individual points in Figure 5 to plot too high. On the other hand it was easy to include in Figure 5 months during which substantial recharge did occur. Such data would plot too low. Therefore, the five points in question probably represent months for which w was not negligible, and they were eliminated from the computations.

The solution of the normal equations for the 18 'fair-weather' months was found to be $C = -4.31$ and $D = -2.54$, or $B = -0.82$ and $A = 0.48$. From (24), the fair-weather equation for the Hulsart well is

$$0.19(\Delta h/\Delta t) = -0.82 - 0.48h \tag{27}$$

The standard error of estimate of $\Delta h/\Delta t$ is 0.72, and the coefficient of correlation is 0.84. Furthermore, from (9) and (11), the ground-water dis-

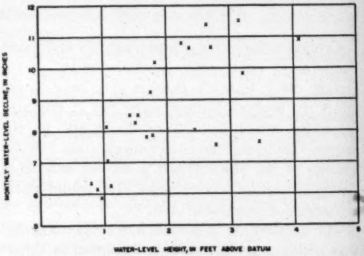

FIG. 5 – Relation between water-level decline and water-level height in the Hulsart well during months when rainfall did not exceed the soil-moisture deficiency

charge corresponding to any height of water table above the datum may be determined. It is

$$q = 0.82 + 0.48h \tag{28}$$

where h is the altitude of the water table in feet above the datum, and q is the rate of ground-water discharge in inches per month.

The result of the January analysis, $S = 0.19$, and the result of the fair weather analysis, $q = 0.82 + 0.48\ h$, may be substituted into (6) to give the full equation for the Hulsart well

$$w = 0.19\Delta h/\Delta t + 0.48h + 0.82 \tag{29}$$

where

$$w = p - e - \Delta v/\Delta t$$

and w cannot be negative, as explained above. Thus, although this expression could not be derived by simultaneous use of all available data, it was estimated from selected parts of the data.

Some important hydrologic quantities can be estimated from the well-trend equations if it is assumed that the Hulsart well is an accurate indicator of the ground-water activity in its area. For example, (29) could be used to estimate evapotranspiration for the Hulsart area if soil-moisture measurements were available. On the other hand, if values of e were available, it could be used to estimate changes in soil-moisture storage.

From (11), $H = B/A = -1.71$ ft below the datum for the Hulsart well. Because the altitude of the datum is 95.59 ft above mean sea level, the base level of flow is 93.88 ft above mean sea level. This figure is in accord with estimates of the altitude of the stream draining the area.

The distance x from the Hulsart well to the nearest stream is approximately 500 ft. The distance L from the stream to the divide is approximately 900 ft. Therefore, according to eq. (11), $T/A = 325{,}000\ \text{ft}^2$. According to the least-squares analysis, A is 0.48 per month. Therefore, T is approximately 40,000 gallons per day per foot in the vicinity of the Hulsart well. The permeability of the Englishtown sand, which underlies the Hulsart area, is highly variable [*Barksdale, Johnson, Baker, Schaefer*, and *DeBuchananne*, 1934, p. 41], and data are not available for an appraisal of this value.

Conclusions—Data from three hydrologically different areas were analysed in order to demonstrate the versatility and usefulness of statistical methods for the analysis of water-level trends. The results are approximate because of the assumptions that were made. However, the purpose of this paper is to demonstrate and encourage the use of these and similar techniques rather than to solve specific hydrologic problems. Furthermore, other hydrologic techniques can not always be used because of limited data. In such cases, these statistical analyses must be considered as preliminary attempts to estimate important hydrologic quantities.

Use of Infiltration Equation Parameters to Evaluate Infiltration Differences in the Field

D. SWARTZENDRUBER AND M. R. HUBERTY

Abstract—The infiltration equations $y = At^B$ and $dy/dt = a + b/y$ have appeared in the literature, where y is the quantity of water which will enter a soil when water is applied to the surface, and t is the time. In the present investigation, the constants A, B, a, and b, are considered for their usefulness in characterizing infiltration in field basins on Greenfield loamy sand, a deep soil without profile development. The product parameter AB is compared with a parameter R_T which is simply the average rate over the first two hours of infiltration. The results show AB to be 40 pct better statistically than R_T. On the other hand, $a + 10b$, which is superior to a alone and b alone, is essentially no better statistically than R_T.

INTRODUCTION

It is well known that the infiltration of water ponded on a soil surface proceeds at a rate which diminishes with time. In some cases a steady value is approached asymptotically, which value has significance in spreading recharge techniques. It does not necessarily have meaning for the irrigationist whose primary concern is with the early stages of the infiltration process. In these stages changes in the slope of the water-time curve are maximal, thus making it difficult to determine the infiltration status of a given soil.

A simple approach to the problem is to specify arbitrarily some constant time interval and express the infiltration status as the average rate of water absorption over the interval. Or, one can use the average rate over the time interval required to absorb a constant quantity of water, as has been done by *Huberty* and *Pillsbury* [1941], *Reitemeier* and *Christiansen* [1946], and *Burgy* and *Luthin* [1956]. Finally, if the infiltration process can be represented mathematically, one could use equation parameters to express the infiltration status. This is the objective of the present paper.

INFILTRATION EQUATIONS

Historical—For one-dimensional downward infiltration, with a film of ponded water, *Gardner* and *Widtsoe* [1921] gave an equation of the form

$$x = c_1t + c_2(1 - e^{-\beta t}) \tag{1}$$

where x is the depth to the wetted front, t is the time, e is the base of natural logarithms, and c_1, c_2, and β are constants. *Horton* [1939] proposed a rate equation which when integrated leads to the form

$$q = f_ct + (f_0 - f_c)(1 - e^{-kt})/k \tag{2}$$

where q is the quantity of water, f_c is the asymptotic steady rate, f_0 is the initial rate, and k is a constant. If the x of (1) is interpreted as the quantity of water q, then (1) and (2) become synonymous since one can set $\beta = k$, $c_1 = f_c$, and $c_2 = (f_0 - f_c)/k$. Eq. (2) attempts a more specific interpretation of constants by the introduction of f_0 and f_c, but is difficult to use since there are three constants to be evaluated experimentally.

A simpler two-parameter empirical equation has appeared in the literature. It is

$$y = At^B \tag{3}$$

where y, expressed as a depth of water, is the quantity of water infiltrated in time t, A is a constant, and B is a dimensionless positive exponent smaller than unity. The year 1926 marks an early attempt to use this equation even though it was not published until 11 years later [*Lewis*, 1937]. *Kostiakov* [1932] considered a functional relation which can be extended to yield (3). *Free*, *Browning*, and *Musgrave* [1940] found that (3) would satisfactorily fit the data for 68 soil profiles, but made no attempt to use its parameters as infiltration indices. However, *Tisdall* [1950] calculated values of A and B for several different soil conditions, and later [*Tisdall*, 1951] correlated both A and B with the level of the antecedent soil moisture.

Horton [1941] has criticized (3) because the differentiated form of the equation implies (i) an infinite initial rate, and (ii) an ultimate final rate of zero. The difficulty in (i) could be removed by adding small constants to y and t in (3), but for most cases of practical interest, these constants would be negligibly small. Hence, (3) suffices unless one is concerned specifically with the behavior of dy/dt for values of time very near zero.

In regard to (ii), no difficulty is encountered if one considers only early and intermediate stages of infiltration. *Tisdall* [1951] reports that (3) will hold up to 16 hours but that A and B can be determined in only a few hours.

Philip [1954] derived an infiltration equation using Darcy's law and several experimental generalizations. It is, with some change in symbols,

$$\frac{dy}{dt} = \frac{k_h}{\mu}\left[1 + \frac{(\bar{m} - m_0)(P + H)}{y}\right] \tag{4}$$

where y is the surface depth of water absorbed, k_h is the conductivity, μ is the viscosity of water, $\bar{m}$ and m_0 are the overall-average and initial moisture contents respectively (volume basis), P is the capillary head, and H is the height of water on the surface of the soil. Eq. (4) is attractive because it is derived theoretically, but investigation shows that the functional relationship which it specifies for y versus t is no different from that found by applying Poiseuille's law to a bundle of circular non-interconnected capillary tubes.

Adaptation and interpretation of equations—If a level field basin is filled with water of depth H_1, the amount of water absorbed with time can be determined by following the subsidence of the water surface with a hook gage. Time is required to fill the basin, and to allow calming of the water surface for the initial measurement. As subsequent measurements are taken, differences z between successive levels and the initial level represent the amount of water absorbed, not from time $t = 0$ but from $t = t_0$, where t_0 is the time of the initial measurement. Assuming that (3) holds from $t = 0$, but that the curve is established only by measurements at t_0 and at times thereafter, (3) becomes

$$z + y_0 = At^B, \tag{5}$$

where y_0 is the depth of water presumed to have been absorbed during the interval t_0. Now $y_0 = At_0^B$, and (5) becomes

$$z = At^B[1 - (t_0/t)^B] \tag{6}$$

The value of B is on the order of $\frac{1}{2}$; in the experimentation to be reported in this study it varied from 0.35 to 0.70. Setting $B = \frac{1}{2}$ in the brackets of (6), putting primes on the A and the remaining B, and dividing through by $(1 - \sqrt{t_0/t})$, leads to

$$z' = A't^{B'} \tag{7}$$

where

$$z' = z/(1 - \sqrt{t_0/t}) \tag{8}$$

Plotting (3) on log-log paper results in a straight line of intercept A and slope B. Eq. (7) will not yield theoretically straight lines when plotted similarly, but up to times t on the order of 1000 minutes, the curvature is negligibly slight. Hence, a log-log plot of (7) is essentially a straight line, but $A' \neq A$ nor does $B' = B$, unless $B = \frac{1}{2}$. By graphing (7) for various values of B and a constant t_0, a curve can be constructed which gives B as a function of B'; also a factor F can be obtained as a function of B', so that $A = A'F$. Thus, if t_0 is made the same for all experiments, and if simultaneous values of z and t are obtained, z' values can be calculated from (8) and a log-log plot of z' versus t will yield values of A' and B' of (7), which finally lead to the values of A and B.

Having shown how to obtain A and B for a field case it is desirable to show how they can be interpreted. It is reasonable to assume that both A and B will reflect soil and water conditions as they affect infiltration. Intuitively, then, it would seem that some combination of A and B might be a better index of infiltration than either A or B alone.

Referring to (3), the average infiltration rate over the time interval t is y/t. Thus,

$$\text{average rate} = y/t = At^{B-1}$$

At unit time, $t^{B-1} = 1^{B-1} = 1$; hence, A is numerically equal to the average rate over the first unit time interval.

If (3) is differentiated with respect to time t, the result is

$$\frac{dy}{dt} = ABt^{B-1} = \text{instantaneous rate}$$

From this it is seen that AB, a combination parameter, is numerically equal to the instantaneous rate at the end of the first unit time interval. If now the ratio of the instantaneous rate to the average rate is formed, the result is

$$\text{inst. rate/aver. rate} = B$$

and B is seen to be synonymous with the ratio of the instantaneous rate to the average rate, the instantaneous rate being measured at $t > 0$, and the average rate being measured over the total time interval t. Thus B is an expression of curvature, and its magnitude indicates how well the infiltration rate will hold up with time.

Another equation can be developed on the basis of (4). Assume that a depth of water H_0 is applied instantaneously to the soil surface in the basin at $t = 0$. Head H decreases with time and is equal to $H_0 - y$, where y is the height of water absorbed. Making this substitution and regrouping terms results in

$$dy/dt = a + b/y \tag{9}$$

where constants a and b are given by $a = k_h(1 - \bar{m} + m_0)/\mu$ and $b = k_h(\bar{m} - m_0)(P + H_0)/\mu$.

Again it is not possible to apply H_0 instantaneously. In practice, H_1 is applied within the interval t_0, during which time the depth y_0 has been absorbed. Hence, as in (5), $y = y_0 + z$, which gives

$$dz/dt = a + b/(y_0 + z) \tag{10}$$

In a plot of dz/dt versus $1/(y_0 + z)$, the slope of the straight line is b, with intercept a. The quantity y_0, made small by keeping t_0 small, is estimated by multiplying t_0 by the rate (estimated from the graph of z versus t) at $t = t_0$.

Parameter a, with dimensions of velocity, is the asymptotic final rate referred to in the introduction, while b, with dimensions of length × velocity, is a measure of the change in rate with depth of water absorbed. On the basis of *Philip's* [1954] derivation, a and b have the further interpretations (as functions of conductivity, moisture, viscosity, and head) given above in connection with (9).

A combination parameter using both a and b can be obtained by choosing some reasonable value of $y_0 + z$ in (10). In the present study this was arbitrarily chosen to be $y_0 + z = 0.1$ ft. Hence, the sum $a + b/0.1 = a + 10b$ is a combination parameter which can be interpreted as the instantaneous rate of water absorption when 0.1 ft of water has moved into the soil.

The quantities A, B, a, and b will contain, implicitly or explicitly, the effects of initial soil moisture, viscosity, and surface head. In any experimentation, these factors must be standardized so that they will not introduce extraneous variations in the infiltration indices.

Experimental Procedure

In May 1955, 32 level basins 10 by 15 ft were constructed on Greenfield loamy sand at the University of California Antelope Valley Field Station, Lancaster, California. Pre-treatment irrigations of four inches of water each were applied on July 12, 18, 25, and Aug. 11. On the last date, subsidence of the water level in each basin was recorded with time.

On Aug. 23, four surface amendments, consisting of ferrous sulfate (1 ton/acre), ferric sulfate (1 ton/acre), gypsum (5 tons per acre) and alfalfa straw (10 tons/acre) were applied at random to 24 basins (6 basins per amendment), leaving 8 basins as untreated checks. On Sep. 8, Sep. 22, Oct. 6, and Oct. 27, four inches of water was applied to each basin and subsidence of the water surface in each basin was recorded with time. Appreciable plant growth was not permitted; water loss from a basin between application dates was limited to evaporation, and seepage into deeper regions of soil. This procedure, along with the pre-treatment irrigations, was necessary to provide uniformity of soil moisture.

In obtaining rate measurements, water was directed into a basin at time $t = 0$, continuing until the water in the basin reached a height $H_1 = 4$ in. (same for all basins). Shortly after, at $t = t_0 = 5$ min, the initial reading of the water level was taken with the hook gage. Additional readings were taken at convenient subsequent times. A photograph of the experimental arrangement is shown in Figure 1.

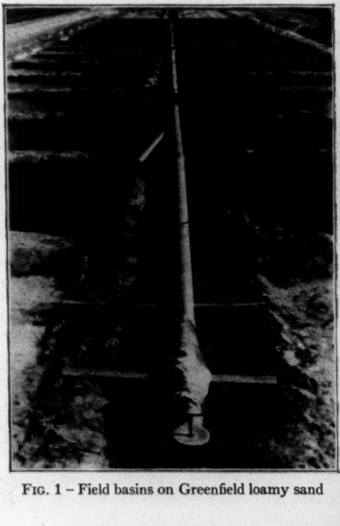

FIG. 1 – Field basins on Greenfield loamy sand

Values of A, B, a, and b were calculated as described in connection with (8) and (10). In addition, R_T, the average rate of water absorption over the first two hours, and R_w, the average rate of absorption during the time required to absorb 0.1 ft of water, were determined. R_T was calculated as the quotient of the value of z at $t - t_0 = 2$ hr divided by 2 hr. R_w was the quotient of 0.1 ft divided by the time (in hr), reckoned from t_0, required for 0.1 ft to be absorbed. Thus, eight parameters, or infiltration indices, A, B, AB, a, b, $a + 10b$, R_T, and R_w were determined for each basin and each date.

COMPUTATIONAL ANALYSIS

Statistical approach—Faced with an array of possible infiltration parameters, one must decide which parameter is best for the objective at hand. In the experimentation just described, the original objective was to assess the infiltration effects of the four amendments as compared to the untreated check. One would choose the parameter which is sensitive to changes in infiltration caused by the amendments, but which at the same time possesses a minimal variance for a given amendment or untreated check. Statistically this is equivalent to choosing the parameter which on the average yields the highest value of Student's t, since this statistical quantity depends upon both the difference between treatment means and the variance among the observations from which the mean is calculated.

For any parameter P (where P might be A, B, AB, a, b, $a + 10b$, R_T, or R_w) on Sep. 8 or later, the observations, or P-values, can be analyzed simply as a completely randomized experiment of five 'treatments' (four amendments plus check). The residual (or 'error') variance is estimated by a pooled overall estimate V, containing 27 degrees of freedom. Multiplying V by $(\frac{1}{6} + \frac{1}{8})$ and taking the square root yields $s_{(\bar{x}-\bar{x}_0)}$, the standard error of the difference between any treatment mean $\bar{x}$ and the check mean $\bar{x}_0$. Then t is calculated in the usual manner as the ratio of $\bar{x} - \bar{x}_0$ to $s_{(\bar{x}-\bar{x}_0)}$.

These amendment-versus-check comparisons do not admit of completely accurate probability statements since they involve non-orthogonal treatment comparisons [*Ostle*, 1954, p. 273]. The inaccuracy, however, is not nearly as extreme as in the calculation of a least significant difference (LSD) since not all possible comparisons are considered. The non-orthogonality could be avoided by calculating individual standard errors for each $\bar{x} - \bar{x}_0$, but this implicitly forces the assumption of a common overall residual variance, which variance should better be estimated by the pooled overall estimate than by individual estimates.

Comparison of parameters—For any single date an analysis of variance, along with the amendment mean differences, leads to four t-values for a parameter P. An analysis of variance for each date results in 16 t-values altogether. Sixteen t-values can similarly be calculated for any parameter P' different from P.

One simple procedure for deciding whether P is better (or poorer) than P' is to adopt a given probability level α and then to choose P rather than P' if P yields the larger number of t-values greater than t_α. A refinement in the procedure would be to vary α from say 1 to 5 to 10 pct and demand, if P is to be termed 'best', that it exhibit a trend of superiority throughout this range of α-values. All possible P versus P' comparisons would then show which parameter, if any, was superior to all of the others.

A more quantitative comparison can be obtained from an average based upon individual comparisons between the 16 corresponding t-values for P and P'. Defining $E(P$ versus $P')$ as an efficiency comparison between P's in which P' is the basis of comparison, $i(= 1, .., 4)$ as the summation index for the amendments, and $j(= 1, .., 4)$ as the summation index for the dates, the comparison is formulated as

$$E(P \text{ vs. } P') = \frac{1}{16}\sum_{j=1}^{4}\sum_{i=1}^{4}\left[\frac{200(t_{ij} - t'_{ij})}{t_{ij} + t'_{ij}}\right] \qquad (11)$$

where t_{ij} is the value of t for the ith amendment and jth date calculated on the basis of parameter P, and t'_{ij} is the similar value of t calculated on the basis of P'. The term in brackets is simply the percentage difference between t_{ij} and t'_{ij}, based upon the mean value of t_{ij} and t'_{ij}.

If $t_{ij} = t'_{ij}$, this is the condition of equivalence between P and P', and $E(P$ versus $P') = 0$. If $t_{ij} > t'_{ij}$ occurs more often and/or to greater degree than $t_{ij} < t'_{ij}$, $E(P$ vs. $P')$ will be a positive percentage and P is considered better than P'. If $t_{ij} < t'_{ij}$ occurs more often and/or to greater degree than $t_{ij} > t'_{ij}$, $E(P$ vs. $P')$ will be a negative percentage and P is considered poorer than P'. Respective maximal and minimal values of $E(P$ vs. $P')$ are $+200$ and -200 pct.

It follows from (11) that the form of the expression for $E(P'$ vs. $P)$, the inverse comparison, is the same as the right-hand side of (11) but with a negative sign. Hence, $E(P'\text{ vs. }P) = -E(P\text{ vs. }P')$, and the magnitude of the efficiency comparison is the same regardless of the order in which E is set up, whether P vs. P', or P' vs. P.

Before the formulation of (11) was decided upon, attempts were made to develop an efficiency comparison involving the ratio t_{ij}/t'_{ij}, but difficulties were encountered. The magnitude of the comparison was not independent of the order of the comparison, nor was the sign always correctly related to the order.

The $E(P\text{ vs. }P')$ of (11) can be further modified to provide an efficiency comparison on the basis of t-values greater than t_α as mentioned earlier. This is done by eliminating from the summation in (11) each (t_{ij}, t'_{ij}) pair in which neither t_{ij} nor t'_{ij} is equal to or greater than t_α. For each (t_{ij}, t'_{ij}) pair eliminated, the 16 in (11) must be diminished by 1. If the modified $E(P\text{ vs. }P')$ remains positive as α varies through a range of values, the trend thus established more than ever indicates P as superior to P'.

[a] On Aug. 23, Basin 9 was treated with alfalfa straw, and Basin 16 with ferrous sulfate, while Basin 3 remained as an untreated check.

Reference data—The pre-treatment data of Aug. 11, hereinafter referred to as the reference data, represent the infiltration status prior to application of the amendments. As has been done by *Huberty* and *Pillsbury* [1941], it appears desirable to utilize the pre-treatment information to reduce variability within treatments. Perhaps the simplest method is to express the basin parameters for Sep. 8 and later as differences from the corresponding reference (Aug. 11) parameters, and then to calculate the analysis of variance and the resulting t-values on the basis of these differences. Designating this procedure as Method II, and the previous analysis of variance (not using the reference data) as Method I, one can for each parameter compare Methods I and II, both on the basis of number of t's greater than t_α, and by the use of an $E(M\text{ vs. }M')$ defined as equal to the right-hand side of (11), where M refers to one method and M' to another, the difference between t_{ij} and t'_{ij} being due to method.

Since overall proportional effects of temperature dependent viscosity and soil moisture can appear from date to date, another reasonable procedure, call it Method III, consists of an analysis of variance of the ratios, expressed as percentages, of the basin parameters on Sep. 8 and later to the corresponding basin parameters on Aug. 11. Comparison of Method III with I and II can be as described in the preceding paragraph.

Finally, one could try a covariance analysis in which the reference parameters (Aug. 11) are treated as the concomitant variable. However, a

complete covariance analysis had to be abandoned after preliminary calculations showed that the regression coefficients inherent to the analysis could not be considered homogeneous.

Numerical illustration—Table 1 sets forth for three different basins the expression of R_T for Methods I, II, and III. The columns headed I contain simply the values of R_T on the various dates. Columns headed II contain R_T as differences from the reference R_T of Aug. 11. Columns headed III contain R_T as a percentage of the reference R_T.

Table 2 contains a complete set of data for R_T, Sep. 8, along with the analysis of variance table and the calculation of a single *t*-value. The calculation of the remaining three *t*-values is not shown. The basic procedure represented in Table 2 was carried through for each parameter, date, and method.

Table 3 sets forth the calculations represented by (11). Each entry in the fourth column is the bracket quantity of (11). Note that $P = AB$ and $P' = B$. From the bottom line of the table the mean value +11.4 indicates AB as superior to B. It can be seen from the fourth column and (11) that $E(B \text{ vs. } AB)$ is −11.4 pct instead of +11.4, showing that the sign of the percentage reflects the order of comparison.

The fourth column also illustrates the modification of $E(AB \text{ vs. } B)$ in accordance with the number of *t*-values greater than or equal to t_α, where $\alpha = 5$ pct. The modified $E(AB \text{ vs. } B)$ is the mean of the eight foot-noted values, rather than the mean of all 16 values, and is equal to the algebraic sum of the foot-noted values divided by 8, or +59.8 pct. When all 16 values are used, the α can be considered as 100 pct.

RESULTS

Validity of equations—If an equation parameter is to be used justifiably as an index of infiltration, it must be demonstrated that the equation itself can be used to represent the infiltration process. The type of agreement obtained for (7) is shown by the representative log-log plots of Figure 2. Of the total number of curves determined, 25 pct exhibited the near-perfect linearity of curve 1 of the figure, and 55 pct showed approximately the linearity of curve 2. Only 20 pct tended to show as much curvature as curve 3. Hence, the success of (7) in fitting these field data is deemed adequate.

The results of fitting the data according to (10) are shown by three representative curves in Figure 3. Thirty-six pct of the curves exhibited the near-perfect linearity of curve 1, while 25 pct exhibited far-end deviation of points similar

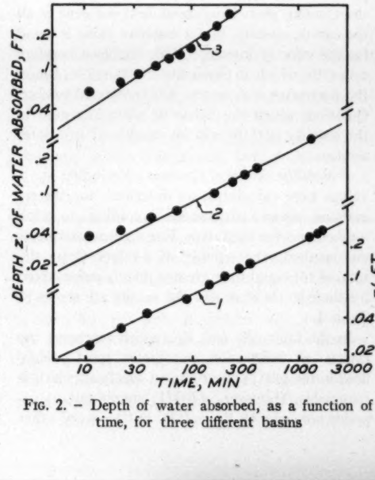

FIG. 2. – Depth of water absorbed, as a function of time, for three different basins

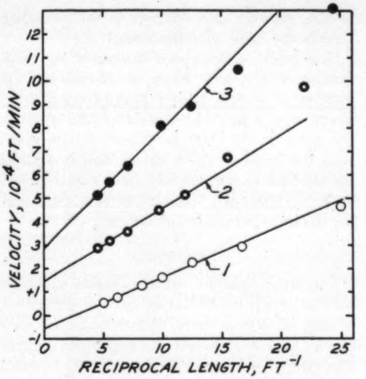

FIG. 3 – Velocity of water absorption, as a function of reciprocal depth absorbed, for three different basins

to curve 2, and 39 pct exhibited far-end deviations similar to curve 3. These deviations, which occur for small values of z [hence large $1/(y_0 + z)$], can be caused by uncertainties in the determination of y_0. The uncertainty becomes negligible as z becomes large enough to dominate $y_0 + z$. Practically without exception the linearity of all curves became almost perfect for the smaller values of $1/(y_0 + z)$.

Even though curve 1 (Fig. 3) shows near-perfect linearity, it illustrates a fundamental shortcoming present in about four per cent of all the curves; namely, that a negative value is found for the velocity intercept. This implies a negative a in (10), which is physically inadmissible; hence, the parameter a alone was not considered further. Questions which this behavior raises in regard to the validity of (10) will be considered in a later section.

Probability levels of t-values—Excluding a, t-values were calculated, as described, for the remaining seven parameters according to each method and for each date. For a given parameter and method, the number of t-values (from the total of 16) equal to or greater than t_α was counted for three levels of α, and the results are shown in Table 4.

In the table, R_T and R_w, which represent the classes of infiltration parameter most widely used in the past, appear almost identical, which is reasonable. However, AB(III) stands out as superior not only to R_T and R_w but to every other parameter and method in the table. The poorest parameter is b, while $a + 10b$ is essentially the same as R_T and R_w. With regard to methods, the order of goodness appears to be III > II > I. For Method I, in which the reference data of Aug. 11 are not used, B appears to be the best parameter. Finally, it also appears that the use of equation (3) is more fruitful than is the use of (9).

Efficiency comparisons—To provide a more quantitative comparison of the parameters against a prevailing type parameter, R_T(III) was chosen as P' in (11) and the other parameters were compared against it. The α-level was varied from 100 pct (or all 16 pairs of t) to 1 pct, and the results plotted as Figure 4A. The logarithmic scale is used simply to emphasize the smaller values of α, which are generally of most interest. Again it is noted that AB is outstanding, while $a + 10b$ is but slightly superior to R_T. Over the whole α-range, B and R_w must be taken as approximately equivalent to R_T, since for large α they are above R_T, and are below it for small α. A, and b especially, are decidedly inferior.

Also illustrated in Figure 4A is the effect of method, as shown by the three different point symbols. Preliminary calculations using (11) for a single parameter but varying methods (see *Reference data*, above) showed R_T(III) to be

TABLE 4 – *Number of t-values equal to or greater than t_α, for each parameter and method*

Parameter	Method	Number of t's $\geqq t_\alpha$

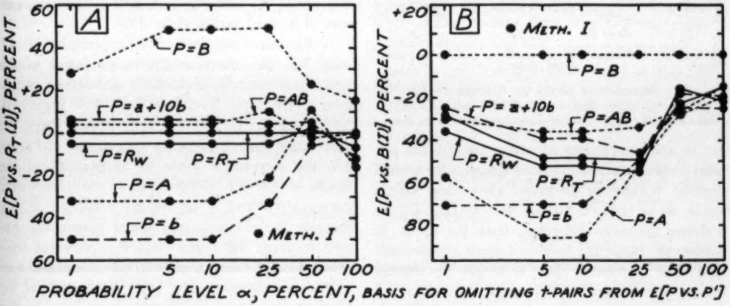

FIG. 5 – Efficiency comparisons for varying levels of probability, basis of R_T(I) and B(I)

superior to R_T(II) and R_T(I). Hence, with R_T(III) as P' in all cases, the efficiency comparison was calculated for each parameter according to each method. Each point used to represent the parameter in Figure 4A was that of the method, I, II, or III, which gave the highest value of the efficiency comparison percentage. It is obvious from the figure that in only a few cases (two) was Method I superior to the others, while for a few more cases (ten) Method II was superior, but in the majority of cases (thirty) Method III was superior. Extensive calculations, not reported here, in which comparisons of II versus I and III versus II were made on the basis of (11), showed conclusively that the order was III better than II better than I, which is in agreement with Table 4 and Figure 4.

Since Figure 4A contains R_T(III) as the basis of comparison, the only strictly accurate comparison involving AB is AB versus R_T. To see whether AB(III) is better than every other parameter and method, it must be made the basis of the comparison [P' in (11)]. Figure 4B, which is similar to Figure 4A except that AB(III) is the basis of the comparison, indeed shows that AB(III) is superior to all other parameters and methods.

The question now arises as to which parameter would be best if reference data were not available; that is, if I were the only possible method. This is shown in Figure 5, in a manner similar to Figure 4. In Figure 5A, the basis of comparison is again R_T, but since B appears best, it is made the basis of comparison in Figure 5B where its superiority is thus established. With the exception of the positions of AB and B, Figure 5 represents essentially the same picture as Figure 4.

Treatment effects—Although treatment effects

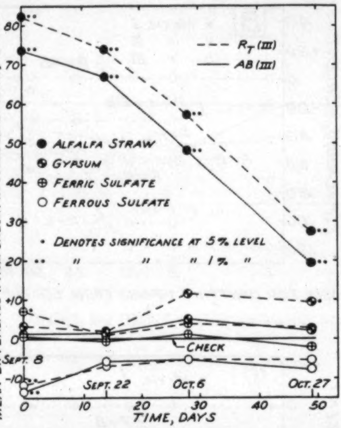

Fig. 6 – Amendment effects as differences from the check, as expressed by R_T(III) and AB(III)

per se and the reasons for them are not the primary considerations of this paper, it is still deemed worthwhile to show what these effects are in terms of both AB(III) and R_T(III). Figure 6 shows the mean difference, from the check, in parameter ratio for each amendment on each date. The 'parameter ratio' is simply the expression of the treatment effect when the reference data are utilized by the ratios of Method III, as illustrated in Table 1.

It is noted from Figure 6 that AB in general produces greater absolute differences than does R_T, as well as an increase from 5 to 7 of results significant at the 5 pct level (see also Table 4). It should be remembered that Figure 6 shows only mean differences, and does not include for AB(III) the additional effect of a lowered 'within' variance, which is included in the efficiency comparisons based on t and shown in Figure 4.

Concluding Remarks

On the basis of the results of this investigation, it can be stated:

(a) The equation $y = At^B$ serves very well to describe short-term infiltration into field basins.

(b) The parameter AB, which can be interpreted numerically as the instantaneous infiltration rate at unit time, is superior statistically to such parameters as R_T and R_w which have been used heretofore.

(c) The equation $dy/dt = a + b/y$, though it represents infiltration data with sufficiently straight lines, possesses one serious physical shortcoming; furthermore, its parameters do not lead to any appreciable statistical advantage over R_T and R_w.

(d) To realize the greatest gain from using $y = At^B$ in evaluating treatment effects of infiltration amendments, it is necessary to obtain pre-treatment measurements of the infiltration status, expressing each post-treatment measurement as the ratio of that measurement to the corresponding pre-treatment measurement.

(e) If pre-treatment measurements cannot be obtained, the use of $y = At^B$ is still better than the use of R_T and R_w, but in this event parameter B is used rather than AB.

A numerical estimate of the superiority of AB over R_T, (b) above, might be expressed as the percentage increase in number of t-values significant at the 5 pct level (see Table 4 or Figure 6). This would be $(7 - 5)100/5$, or 40 pct. From the more quantitative efficiency comparison of Figure 4A, the increase is given as 57 pct. Thus, the figure of 40 pct would seem to be sufficiently conservative and is tentatively accepted as the increase in efficiency one might reasonably expect in using AB rather than R_T, provided that pre-treatment measurements are available.

The advantage of the ratio method (that is, Method III) listed in (d) above is probably the result of two overall proportional effects: viscosity and moisture content. Flow of water is inversely proportional to the viscosity which in turn is temperature dependent. Temperature changes over the period from Aug. 11 to Oct. 27 would thus induce proportional effects into the flow parameters. Furthermore, on the basis of *Neal's* [1938] experiments, one can reason that progressive changes in the overall moisture content over the same time period could also, at least to a first approximation, induce proportional effects in the flow parameters. The ratio method removes these elements of variability.

The failure of the equation $dy/dt = a + b/y$ to yield parameters of appreciable statistical superiority, along with a tendency to predict physically inadmissible negative values of a, argues against using this equation for the specification of infiltration characteristics. However, it must be remembered that the theoretical derivation of (4) assumes all flow to be vertically downward. For the basins studied here (10 by 15 ft), the relative amount of lateral flow probably comes much closer to being negligible than it does for a small ring infiltrometer less than one square foot in cross section. However, this still does not quarantee that lateral movement for the basins was negligible; hence, the shortcomings of the equation may have been due to such lateral movement. To clear up this point, further investigation is needed.

Because of the success of the equation $y = At^B$, both physically and statistically, it would appear that future investigations involving infiltration might well be improved by the use of this equation and its parameters for specifying the short-term infiltration status of a soil.

Problems Encountered in the Utilization of Ground-Water Reservoirs

RAPHAEL G. KAZMANN

Abstract—Ground-water reservoirs are compared to surface-water reservoirs and the similarities and differences are pinpointed. For example, the boundaries and storage capacity of a water-bearing formation are not readily determinable. By comparison, an aerial survey of a potential reservoir site, from which a contour map may be prepared, is generally sufficient to determine the boundaries and storage capacity of any desired impoundment. Further, ground-water reservoirs are full to start with, whereas the area of an impoundment is usually devoid of water, except for a small amount contained in the river channel. Such differences, and others discussed in the body of the paper, give rise to social and engineering problems which are not duplicated elsewhere in the field of water-resource development. It may not be an exaggeration to state that, at our present level of technique and knowledge, the scientific and engineering problems are less vexing than the problems which must be solved by negotiation and persuasion. Examples of problems encountered in the utilization of ground-water reservoirs are cited. As case histories, problems of industrial ground-water supply in the East St. Louis area, and of municipal ground-water supply in the Canton, Ohio, area are discussed.

Definition of a reservoir—All functional reservoirs, surface and sub-surface, have certain characteristics in common. Any functional reservoir must admit water, store water, and permit water to be withdrawn economically. If an aquifer does not admit water but contains water and permits it to be withdrawn, it is not a functional reservoir, it is a mine. If it admits water and releases water, but does not store water, it is not a functional reservoir, it is a channel.

The differences between surface and sub-surface reservoirs are, of course, the source of the special problems connected with the utilization of aquifers. A point-by-point comparison is illuminating.

Reservoir capacity—The boundaries of a surface reservoir and its capacity are readily and rapidly determinable. Aerial photos combined with radar profiles and stereoscopic plotting, requiring only a minimum of ground control, will generally enable preparation of a contour map which can be used as the basis for selecting and evaluating dam sites in terms of potential impoundments.

Not so water-bearing formations. Not only is it a time-consuming, expensive task to delineate the boundaries of an aquifer, but the water-bearing materials are likely to be heterogenous, contain lenses of clay or silt, and be of different permeability in different places. Moreover, the storage coefficient of an aquifer can assume different values in different places and may change significantly, possibly by three orders of magnitude, as the aquifer is progressively dewatered or filled.

In addition to mapping, much test drilling, aquifer-performance testing, and hydrogeologic interpretation is required to determine the storage capacity of an aquifer. The work is complex, relatively expensive, and time-consuming. Moreover, the results of the work have a greater uncertainty factor than the analogous study of a potential surface impoundment.

Reservoir condition—A surface reservoir site is generally devoid of ponded water before an impoundment is created. A ground-water reservoir is usually full of water initially. This has certain social implications which will be touched upon later, and creates a series of problems of engineering negotiation that are not encountered elsewhere.

The quality of reservoir water—The approximate quality of water to be expected in a surface impoundment can be predicted in advance of construction by taking and analyzing samples from the water source over a period of years.

Not so a water-bearing formation. Samples of water from an aquifer may be satisfactory, but mineralized water may overlie or underlie the aquifer and the exact quality of water to be obtained may change with the rate and distribution of the offtake. In certain instances even after the most exhaustive studies the future quality of water may be more or less indeterminate. Evaluation of the quality of water to be expected from an aquifer is a matter of judgment, after the facts have been collected, assembled, and analyzed.

The filling and emptying of reservoirs—The usual surface impoundment is filled rapidly and at the maximum possible rate by the unrestricted flow of water in the river which has been dammed. It is discharged at any desired rate by opening a gate or valve, as required. There is little or no 'feed-back' effect. The rate of replenishment is not limited when the reservoir is not full.

Not so a sub-surface reservoir. Sub-surface reservoirs are replenished by water infiltrating from a surface source either by percolation from precipitation or by infiltration of water from a river which intersects the recharge area. Excluding limestone or basalt aquifers, which are recharged through sink-holes or fissures, the limit to the rate of recharge depends on the permeability of the outcropping materials and, probably equally important, on the hydraulic gradients created by the distribution of pumpage within the aquifer; that is, the rates and positions of the offtakes. Recharge is, therefore, dependent upon a factor that cannot be exactly evaluated before the aquifer is developed. This feed-back effect is a major factor in determining the rate of recharge.

Note that the bottleneck in recharge is matched by a bottleneck in offtake. Taking water from the ground-water reservoir is not a simple matter of opening a gate. The process involves construction of wells, and installation of pumps and power source. Even then, the amount available at any point of offtake is limited, in a complex manner, by the hydrogeological characteristics of the formation, the design of the well, and the pumpage from nearby wells.

The availability of recharge—In a surface impoundment, water entering one part of the reservoir immediately raises the level of water throughout the reservoir and thus makes all of the stored water more readily available for use.

Not so a sub-surface reservoir. Due to the slow movement of water through porous media, a reservoir may be replenished in one area and remain unreplenished in most of the area that it underlies. Thus the mere fact of recharge does not of itself assure us that a proportionate supply of ground water will be available throughout the aquifer. This important characteristic of aquifers is often overlooked in practice.

Negotiating problems—Even this brief summary may be sufficient to indicate the physical and technical differences between ground-water reservoirs and surface impoundments. A short discussion of the social problems and negotiating difficulties is now in order.

A surface reservoir lends itself to centralized control: land acquisition must occur in a large block, construction is large-scale, and operation is visible and readily controlled with a minimum of effort. Visible benefits such as flood control, irrigation, hydropower, water supply, and recreation may result from a single impoundment (although the operational requirements of each of these functions are not always compatible, especially as the size of impoundment increases and with it the possibility of year-to-year carry-over of stored water).

Utilization of aquifers has been more haphazard and the result of the initiative of individuals rather than governmental or collective effort. The replenishment of the aquifer, everybody's business, is nobody's business, until water levels drop. Aquifers contain a maximum quantity of water at the start of development and, because the amount in storage is so much greater than any possible surface impoundment, the supply is usually regarded as unlimited. It has generally happened that by the time collective action becomes necessary, a complex tangle of economic and legal relationships has been created and there are vested interests which operate on mistaken hydrogeologic assumptions.

Moreover, the technical problems of different aquifers are not identical. Unhappily, experience in negotiating a solution in one place is only generally helpful in solving problems in another place. For instance, the organization of a 'district' for artificial recharge to replenish an irrigation supply will differ considerably from that of a recharge 'district' organized to prevent intrusion of mineralized water to a fresh-water aquifer. It may be anticipated that a wide variety of administrative organizations, private and public, will be needed to cope with the many aspects of problems involved in the utilization of ground-water reservoirs, in contrast to the relatively few forms of the surface-water control district. Thus, skill at negotiation, and a broad, open-minded approach to the problem of utilization of aquifers, is essential. Even the most junior members of a technical organization must exercise tact and discretion lest, by some ill-considered statement, adverse public opinion be developed which will impede the purely technical program of study while, at the same time, hastening the organization of opposition to the subsequent recommendations.

Reasons for developing ground-water reservoirs—In reviewing the many complex problems in the field of ground water, problems which are difficult and expensive to solve, one may ask why development is justified at all. And this is probably the most important single question that must be answered. In the United States there is at least one hundred times as much water contained in aquifers as in all of our existing man-made impoundments. Since these water-bearing formations are approximately full to start with, the water can be obtained cheaply by individuals. This water is especially attractive during the first two or three decades of development since it is more reliable and can be brought into operation more rapidly than any comparable river source. When the water-bearing formations have been depleted, the potential reservoir capacity usually remains. It is of utmost importance to a nation that this reservoir capacity be utilized. Aquifers must be transformed from mines to reservoirs; the cost of study is minor compared to the cost of obtaining the same volume of storage in some other way.

Considered as storage reservoirs, aquifers are not subject to evaporation losses, they are not progressively reduced in capacity by deposition of sediment, no land is removed from cultivation, and last, but unfortunately of increasing importance, water in aquifers composed of granular materials is almost completely protected from radioactive fallout.

The problems of the continuing use of ground water are not problems of vast reclamation projects, which assume *a priori* the economic value of the results to be obtained by impounding vast volumes of water, and which are justified by postulated cost-benefits ratios. On the contrary, the substantial investments already in existence justify the costs of transforming ground-water mines into ground-water reservoirs. And although the cost of studies may seem high compared to the cost of analogous studies for storage of water upon the land surface, the cost of the projects is low compared to the cost of the same size water-storage development on the land surface.

The principal technical problem in the field of ground water is to devise a method for economically changing ground-water mines into reservoirs. The principal negotiating problem is to obtain the needed legal rules so that the technicians may do the most effective job in applying the techniques. At this time (1957), in my opinion, both problems await satisfactory solution.

Case histories—(1) The American Bottoms area, the flood plain of the Mississippi River opposite St. Louis, is a genuine ground-water reservoir. The sediments, mostly sand and gravel which were deposited in the bedrock channel of the Mississippi River some 20 to 30 thousand years ago, are permeable. Water withdrawn from wells is replaced by infiltration of water from the Mississippi River and by percolation of precipitation from the land surface. Total quantity of water in storage is about a million acre feet, comparable to the projected storage at Folsom Reservoir or Pine Flat Reservoir. It is one of the Nation's smaller ground-water reservoirs.

Annual ground-water offtake, replenished without special man-exerted effort, is estimated at about 15,000 acre feet a year. Computations show that by means of proper organization and construction, the total perennial supply could be raised to about 75,000 acre feet a year without artificial recharge, merely by positioning well fields in such a manner as to increase the natural recharge.

Single horizontal collectors, built on the river bank are operating at offtake rates of more than 10,000 gpm each. These are large, expensive units and their potential yields must be accurately determined in advance of construction. This is accomplished on the basis of the results of aquifer-performance tests, which give the effective transmissibility and effective distance to the 'line of recharge,' which data combined with information on stages of the river and water temperature, is the basis for computation.

The stage of the Mississippi River at St. Louis has been recorded daily since 1861, so the mean annual stage can be readily determined from a gage-height duration curve. The mean daily and monthly discharges are also a matter of record. We can also determine the frequency of any selected stage that has occurred and thus design conservatively. What, then, is the problem?

In the interest of navigation, the channel has been straightened and deepened. In the interest of flood control, levees have been built to constrict the flood flows. Thus at low rates of river flow the gage height is being progressively reduced because of channel improvements, whereas at flood discharges the gage height is being increased. This tends to distort and lower the position of the gage-height duration curve. Instead of the recorded mean river stage, elevation 390, we compute a mean river stage under present conditions of channel of, possibly, 387. Moreover, there is no assurance that, in the life of our installations this mean stage may not go down to 385. The situation makes for difficulty in computation and, because of reduction in head of the recharge water, for decreasing ground-water yields. But by judicious extrapolation of trends, decisions can be made; after all the mean annual discharge from a 700,000 sq mi drainage area is not likely to be changed. Nor will the mere redistribution of flood flows, by means of flood-control reservoirs such as those at

Garrison, North Dakota, and Oahe and Ft. Randall, South Dakota, and Fort Peck in Montana significantly change the mean annual discharge. Total usable storage when these and other reservoirs are completed will be about 60 million acre feet. By way of comparison the average annual discharge of the entire Mississippi-Missouri River System at St. Louis for the decade starting in 1940 was about 130 million acre feet.

Now, if the nature of the upstream developments were purely a matter of flood control it would not be very difficult to make an operational analysis of the system, including the effects of the flood-control reservoirs, and compute a useful, synthetic gage-height duration curve for, say, a 30-year period of record, using the observed discharges and modifying them in predetermined manner by the release of flood waters. This synthetic gage-height duration curve would enable us to determine probable future river levels and would substitute admirably for the now-valueless hydrographs of the river.

But, no. The storage of flood waters in the upper Missouri Basin has given rise to irrigation projects. The future consumptive use of water in the Missouri Basin for irrigation is now estimated at an average of 10 million acre feet a year. Naturally, during a dry period, this figure will rise and during wet years it may decline. Thus our operational analysis becomes exceedingly complex and, certainly, the average yearly discharge of the Mississippi at St. Louis will be at least seven per cent smaller due to consumptive use of irrigation water. In some years, like 1940, the annual flow might be reduced by 15 pct and the flow in a given month even more. It is virtually impossible to predict the occurrence and duration of low water periods and, for a ground-water supply replenished by river infiltration, these are crucial. There is no answer yet to this problem and no immediate answer should be expected, the hydraulic system is not in a state of steady-flow and the feedback effect is very large. The design of important ground-water facilities has become increasingly difficult due to the lack of assurance as to the probable reproducibility of past hydrologic events.

(2) A ground-water reservoir problem that was solved in a satisfactory manner is located near Canton, Ohio. In 1946, following general studies by the Ohio Water Resources Board and the Ground Water Branch of the U. S. Geological Survey, the City decided to have detailed engineering studies made in an area it owned in the northwest section of town (Fig. 1). There is a buried valley running in a southwesterly direction. On the land surface a small stream, West Branch of Nimishillen Creek, intersects the ancient buried valley. Exploration and aquifer-performance tests showed that there were two aquifers in the area, separated horizontally by a tough, impermeable clay which was probably deposited during a long period of ponding after the first retreat of the glaciers. Figure 2 shows the two piezometric surfaces and their relationship to the buried valley. The aquifers are demonstrably separate.

This was the situation: the upper aquifer was in

contact with the stream and would obtain water from it to replace water pumped by wells. But the stream is intermittent and is dry during a fraction of the year. It would be necessary to draw from storage in the aquifer during about half of the time. The upper aquifer ranges in thickness from 20 to 40 ft and it can be shown that the useable quantity of water in storage is inadequate to assure the desired yield of 7000 gpm or ten million gallons a day.

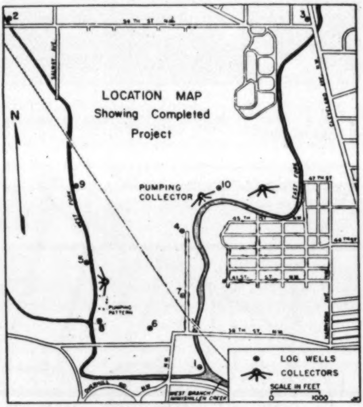

FIG. 3 – Relationship between the 'outriding' recharge units and the dual-purpose pumping unit

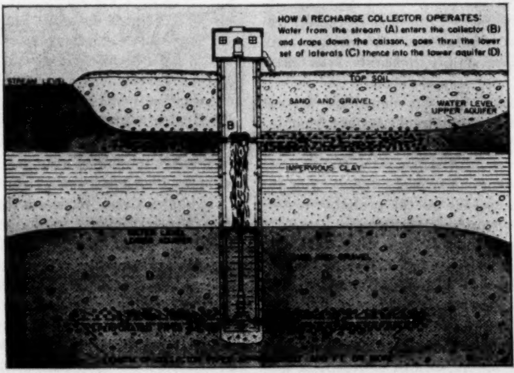
From an engineering viewpoint the deep aquifer, although it contains a tremendous amount of water in storage, had to be treated as a potential water-mine rather than as a reservoir because the rate and occurrence of recharge was unknown, and it was certainly not under the control of the City of Canton.

The technical problem thus resolved itself into finding a method of utilizing the upper, thin, aquifer as a filter plant and connecting it with the lower aquifer, which would then be transformed into a functioning reservoir. The negotiating problem was to convince the authorities in Canton that this was both feasible and worthwhile.

The solution to these problems was undertaken by Eugene Silitch (then President and Technical Director of Ranney Method Water Supplies) and the writer (who was at that time Chief Hydrologic Engineer of that Company). After many computations, which involved preparation of synthetic flow-duration curves, estimates of the filter-plant capacity of the stream bed under various conditions of head, and calculations of infiltration capacity, collector yield and interference, it became clear that the best technical solution would be to build three dual-purpose horizontal collectors and to equip only one of them with pumps. Figure 3 shows the relative position of the units. Pumps were installed in the middle collector, the other two serving solely for the purpose of recharge. Figure 4 shows how a recharge collector operates.

From a negotiating standpoint the problem was very difficult. The situation had to be presented so



HOW A RECHARGE COLLECTOR OPERATES: Water from the stream (A) enters the collector (B) and drops down the caisson, goes thru the lower set of laterals (C) thence into the lower aquifer (D).

FIG. 4 – Schematic cross section of the dual-purpose horizontal collector

clearly and conclusively that the city officials who possessed no familiarity with ground water, would agree to the construction of the two outriding collectors. These units, not having pumps, would not be of any visible benefit to the City. The negotiations, which amounted to a cram post-graduate course in the field of ground water were successful. The system was built as designed and has been operating for the past eight years to the entire satisfaction of all concerned.

This project illustrates how important skilled negotiating is to the successful accomplishment of technically complex ground-water projects. Without construction of the two outriding dual-purpose units, the project would have been of questionable value, with little assurance of maintaining the desired rate of offtake. Yet the position of the negotiators, confronted with the necessity of persuading responsible officials to approve the installation of two apparently useless horizontal collectors was an awkward one, because the value of the construction would not become manifest until a major dry period.

Conclusion—A scientific solution to almost any ground-water problem can be devised. An engineering solution, more difficult to achieve, is sometimes feasible. But the skills involved in negotiating and achieving a sound engineering solution are rare. There are no texts to study. A newcomer can only learn by example how to bring negotiations to a successful conclusion.

The future of the utilization of a region's water supply lies in the science, engineering, and negotiation needed to transform ground-water mines into ground-water reservoirs. There is much work to be done in all of these fields.

Upper and Lower Frequency Curves for Peak Rates of Runoff

W. D. POTTER

Abstract—Maximum annual peak rates of runoff plotted on extremal probability paper have many times been found to exhibit trends that may be defined by two straight lines designated as upper and lower frequency curves. Using a sample of 69 gaged watersheds with periods of record ranging from 26 to 48 years, a high degree of correlation is found to exist between the upper and lower frequency curves for 10- and 50-year recurrence intervals. Tests are made to show that these relations may be used in conjunction with periods of record as short as ten years to materially improve the precision of estimates of peaks on the upper frequency curve.

Evidence is presented that suggests that the dog leg in frequency curves is the result of sampling from two different populations of peak rates of runoff.

Introduction—It has often been observed by engineers and hydrologists who have had occasion to make probability studies of maximum peak rates of runoff that when these peaks are plotted on extremal probability paper they many times do not exhibit a straight line trend but rather one that is better defined by either a curve or by two straight lines. This dog leg (two straight lines) in the frequency curve is not limited to a few isolated locations but is quite general for streams located in the central and eastern portions of the country and is especially noticeable when the period of record is 25 years or more.

Upper and lower frequency curves—Figures 1 and 2 are two of the many illustrations of the dog leg in the frequency curve that might have been selected. The lower graph in each figure shows the maximum annual peaks for the entire period of record plotted on extremal probability paper. The right-hand branch of the dog leg, designated as the upper frequency curve, is the average curve for those peaks that have an indicated average recurrence interval equal to or greater than five years. Points on this curve are designated by subscripts such as Q_{10U}, Q_{25U}, etc. The numerical portion of the subscript indicates the average recurrence interval and the letter the upper frequency curve.

The left-hand branch of the dog leg, designated as the lower frequency curve, is the average curve for those peaks that have an indicated average recurrence interval of less than five years. Points on this curve are also designated by subscripts similar to those used on the upper curve except that the letter L replaces U to indicate the lower frequency curve as Q_{10L} or Q_{25L}.

Short records; a source of error—The upper graph on Figures 1 and 2, shows the frequency curve based on only ten consecutive years of record. For these short periods the dog leg is not apparent and the trend of the plotted points is one straight line. In Figure 2, the highest peak of 20,000 cfs was not considered in drawing the average frequency curve. This peak plotted so far off the line defined by the other nine peaks that it was assumed to have an average recurrence interval of approximately 200 years rather than the 11 years indicated by the theoretical plotting position. Note, however, that when the entire 29 years of record are used, this peak is consistent with the other peaks that define the upper frequency curve.

If it were assumed that only the ten years of record shown on the upper graphs were available and an estimate were desired of the 10- and 50-year peaks, they would have been those indicated by the average frequency curves. For the Sabine River, the estimate for Q_{10} would have been 113,000 cfs and for Q_{50} 168,000 cfs. If the entire record of 29 years had been available and the estimates taken from the upper frequency curve, they would have been 82,000 cfs for Q_{10U}, and 130,000 cfs for, Q_{50U}. The differences between, Q_{10} and Q_{10U}, and between, Q_{50} and Q_{50U}, expressed as a percent of, Q_{10U} and Q_{50U}, respectively, are measures of the errors that would have resulted from the use of the short term record. For the Sabine River, these errors would have been +38 pct for the estimate of the ten-year peak and +29 pct for the 50-year peak.

In a like manner, the errors of estimate for the 10- and 50-year peaks of the Flat River would have been, −9 and −28 pct, respectively.

Figures 1 and 2 illustrate the difficulties that are encountered when a sampling procedure is used to obtain estimates of peak rates from ungaged watersheds in any physiographic area. When short records are included in the sample of gaged watersheds to obtain peak rates for some reccurrene interval, errors of unknown sign and unknown magnitude are introduced. These errors may well obscure any relation that may exist between the true peaks for this recurrence interval and some independent variable such as watershed area. On the other hand, if only long records are used in the sample of gaged watersheds, the sample is apt to be so small as to be nonrepresentative of the area and watershed size groups being sampled.

Relations between frequency curves—If it could be shown that a high degree of correlation existed between the lower and upper frequency curves and if the lower frequency curve could be defined with sufficient accuracy by short-term records, then a way would have been found to increase the precision with which peaks having recurrence intervals equal to or greater than five years could be estimated from short periods of runoff records. More specifically, if a high degree of correlation existed between, Q_{10L} and Q_{10U}, and between, Q_{10L} and Q_{50U}, then this relation could be used in conjunction with values of Q_{10L}, determined from short records to provide estimates of the upper frequency curve. These estimates would have a known degree of accuracy provided the lower curves were sufficiently defined by the short runoff records.

To investigate this possibility, a sample of 69 watersheds was selected having periods of record of from 26 to 48 years and ranging in size from 3 to 6000 sq mi.

The maximum annual peaks for each watershed were plotted on extremal probability paper and the upper and lower frequency curves determined. Since the lower frequency curve, in most cases, was clearly defined by the plotted points, it was fitted by eye. The upper frequency curve, however, was a computed least-squares curve. From these frequency curves, values of Q_{10L}, Q_{10U}, and Q_{50U} were tabulated (Table 1). For each watershed, Q_{10L} was plotted against Q_{10U} on log-log cross section paper and an average least squares curve was computed for the 69 points. The equation for this curve is

$$\log Q_{10U} = 0.109 + 0.984 \log Q_{10L},$$

where Q_{10L} and Q_{10U} are expressed in 1000 cfs (Fig. 3). In a like manner values of Q_{10L} were plotted against corresponding values of Q_{50U} and an average least squares curve computed. The equation for this curve is

$$\log Q_{50U} = 0.273 + 0.985 \log Q_{10L},$$

where Q_{10L} and Q_{50U} are expressed in 1000 cfs (Fig. 3).

Both graphs show a high degree of correlation, 68 pct of the plotted points falling within ±10 pct error bands for the Q_{10L} versus Q_{10U} graph and within ±20 pct bands for the Q_{10L} versus Q_{50U} graph. It is estimated that these errors are approximately one-half to one-third those that might be expected if estimates of Q_{10U} and Q_{50U} were to be determined directly from single-frequency curves based on short periods of record.

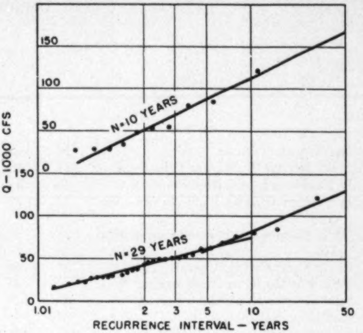

FIG. 1 – Frequency curves, Sabine River near Ruliff, Texas

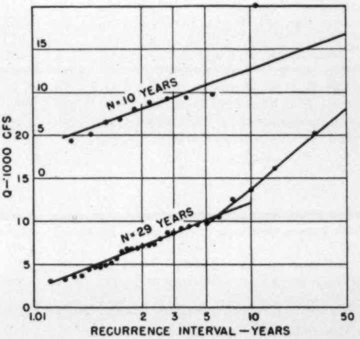

FIG. 2 – Frequency curves, Flat River at Bahama, N. C.

Use of relations to reduce error—Tests were now made to find the minimum length of record required to determine Q_{10L} with a sufficient degree of accuracy. Two 15-consecutive-year samples were selected from the record of each of the 69 watersheds. The beginning or end of these periods was determined by drawing a number from a stack of numbered cards. The number drawn indicated either the years of record that preceded

[a] Estimate from average curve.

the first year of the 15-year period or, if the remaining years of record were less than 15 years, the number drawn indicated the next following the last year of the 15-year period. For example, if the period of record were 30 years and the number five was drawn, the first year of the 15-year period would be the sixth year of record, the second year the seventh year of record, etc. If, however, the number 25 was drawn, the fifteenth year of the 15-year period would be the twenty-fourth year of record, the fourteenth year the twenty-third year of record, etc.

For each 15-year sample, estimates of Q_{10L} were determined by fitting by eye of average curves drawn through the maximum annual peaks plotted on extremal probability paper. In drawing these curves, only those peaks whose plotting position indicated an average recurrence interval of less than five years were considered. For each sample values of $\hat{Q}_{10L}$ (the estimates of Q_{10L}) were plotted on log-log cross section paper against the corresponding values of Q_{10U} and Q_{50U}, previously determined by least-squares curves based on entire periods of record.

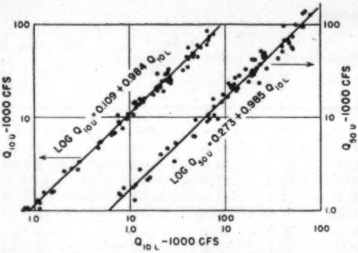

FIG. 3 – Relations between Q_{10L} and Q_{10U} and Q_{10L} and Q_{50U}

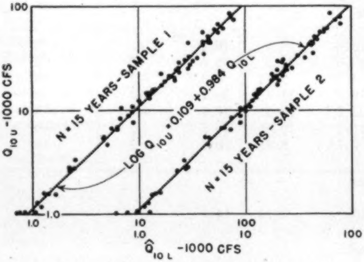

FIG. 4 – Relation between $\hat{Q}_{10L}$ and Q_{10U} for 15-yr samples

Figure 4 shows the, $\hat{Q}_{10L}$ versus Q_{10U}, graphs for each 15-year sample. The line drawn through each set of plotted points is the average least squares curve computed for the Q_{10L} versus Q_{10U} graph (Fig. 3), and based on the entire period of record. Since this curve is also a good average curve for both 15-year samples and since 68 pct of the plotted points for each graph falls within ±10 pct error bands, it was concluded that neither the relation between Q_{10L} and Q_{10U} nor the precision with which Q_{10U} could be estimated was altered materially by the use of 15-year records to define Q_{10L}. Likewise it was found that the precision that might be expected in estimating Q_{50U} and the relation between Q_{10L} and Q_{50U} as derived from the 15-year samples remained substantially the same as those computed from the entire periods of record.

In a manner similar to that described for 15-year samples, two ten-year and two five-year samples were selected and tested. For the ten-year samples, both the average curves and the precision that might be expected from estimates were found to be approximately the same as those computed from the entire record. For the five-year samples, however, it was found that, although the average curves remained unchanged, the precision that might be expected from 68 pct of the samples was decreased by approximately five per cent.

These tests would indicate that in physiographic areas where nearly constant relations exist between the upper and lower frequency curves, those relations may be used to advantage in conjunction with periods of record as short as ten years to improve the precision of estimates of peaks on the upper frequency curve.

Cause of dog leg—Two propositions are advanced to account for the dog leg in frequency curves. (1) The period of record is too short to define accurately the true recurrence intervals for the higher maximum annual peaks. (2) The samples of maximum annual peaks are drawn from two different populations.

If the first proposition were true, then the upper and lower frequency curves could be expected to become one and the same curve as the period of runoff record N were increased. Likewise, for any recurrence interval, the ratio of the upper curve value to that of the lower curve could be expected to approach unity as N became larger and larger.

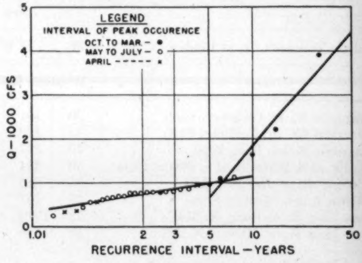

FIG. 5 – Frequency curves, South Fork Silver Creek near Ice House, Calif.

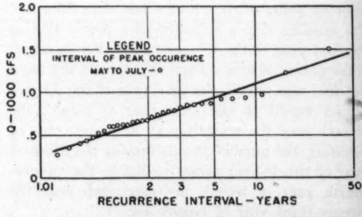

FIG. 6 – Frequency curve, Bear Creek near Vermillion Valley, Calif.

A partial test of the authenticity of this proposition was made with the 69 watersheds tabulated in Table 1. For each of these watersheds, values of the ratio of Q_{60U} to Q_{60L} were determined. The watersheds were then divided into three groups in accordance with the length of runoff record. The first group consisted of 23 watersheds whose period of record varied from 26 to 30 years. The second group contained 28 watersheds with periods of record varying from 31 to 35 years. The third group had 16 watersheds and periods of record varying from 36 to 40 years. The mean and standard deviation of the ratio of Q_{60U} to Q_{60L} for the three groups were as follows: Group 1, mean ratio = 1.18, standard deviation = ±0.29; Group 2, mean ratio = 1.17, standard deviation = ±0.22; Group 3, mean ratio = 1.22, standard deviation = ±0.18.

From the above comparison it is evident that there was no significant change in the ratio of Q_{60U} to Q_{60L} that could be attributed to a change in the period of record within the range of 26 to 40 years. The decrease in the standard deviation with an increase in N indicates a closer grouping of the ratio about the mean and is probably due to a more precise definition of the upper frequency curve as more upper curve peaks were included in the runoff record.

Although definite proof that the second proposition is invariably the true explanation of all dog legs in frequency curves is still lacking, one case will be cited where the second proposition undoubtedly did account for this phenomenon.

Twelve gaged watersheds located in northern California on the western slope of the Sierra Nevada were selected for study. These watersheds had uncontrolled surface runoff, ranged in size from 23 to 845 sq mi, and had runoff records of from 28 to 40 years. When the maximum annual peaks were plotted on extremal probability paper, it was discovered that ten of the 12 watersheds had a very pronounced dog leg in their frequency curves. The two exceptions had no dog leg at all, the frequency curve being one continuous straight line. Figures 5 and 6 are typical examples of these two types of frequency curves.

When the maximum annual peaks were classified as to the month in which they occurred, it was found that the large majority of peaks on the lower frequency curve occurred during the period May to July or during the month of April. Since little or no rain is experienced during May to July, those peaks that occurred during this period must have been caused by snow melt. Those that occurred during April could have been caused by rain or snow melt or by a combination of both. On the other hand, almost 100 pct of the peaks on the upper frequency curve occurred during the period of October to March and were the result of winter rains (Fig. 5).

The two watersheds whose frequency curves were single straight lines had average elevations of over 9000 ft. The maximum annual peaks all occurred during the period May to July and were the result of snow melt, (Fig. 6).

In this case there can be little doubt that the dog leg in the frequency curves was caused by the sampling of two populations, namely, peaks caused by rain and those caused by melting snow. Where the sampling was limited to only one population, peaks caused by snow melt, there was no dog leg and the frequency curve was defined by one straight line. This suggests that a similar phenomenon could result when peaks caused by either two different storm types (such as frontal and convectional) or by two different watershed conditions (optimum for high rates of runoff and intermediate for lesser rates) [*Potter*, 1949, 1951] are included in one sample.

Discussion—No attempt has been made in this paper to establish that the dog leg in frequency curves is a characteristic of all frequency curves of maximum peak rates of runoff or that the same correlation between the upper and lower frequency curves may be applied to all cases where the dog leg is found to exist.

Rather, an attempt has been made to illustrate that the presence of the dog leg is common to the frequency curves of watersheds in widely separated locations and that, where a high degree of correlation can be established between upper and lower frequency curves, it may be used to increase the precision of estimates based on short periods of runoff records.

Evidence has been presented that, although it does not definitely establish the cause or causes of the dog leg, lends weight to the proposition that it is the result of sampling from two populations of maximum annual peaks.

A Long-Period Seismograph System*

FRANK PRESS, MAURICE EWING, AND FRANCIS LEHNER

Abstract—A matched three-component seismograph system operating with pendulum period of 30 sec and galvanometer period of 90 sec is described. As a result of increased sensitivity for periods greater than 20 sec, seismograms from these instruments contain information not previously available.

Introduction—The advantages of a seismograph system consisting of three matched components are well known. Instruments incorporating this feature were built by Galitzin, *Benioff* [1955], and Hiller. In this paper we describe a system of longer period than any of these, designed to improve the recording of seismic body and surface waves of longer period.

It is desirable to limit the response of such a system in the short-period range. This would minimize the response to microseisms (which limit the usable sensitivity of any seismograph system) and bring out long-period phases which are obscured by shorter period vibrations on standard seismograms. The major problem was that of constructing a stable vertical pendulum with a period of about 30 sec. A solution was found by using the zero-length spring principle of *La Coste* [1934] and the recently developed isoelastic spring materials, and by compensating for the buoyant effect of atmospheric pressure fluctuations.

Since 1951, a buoyancy compensated vertical seismometer [*Ewing* and *Press*, 1953] with periods of 15 and 90 sec for pendulum and galvanometer, respectively, has been operated at Palisades. The expected advantages of the instrument were quickly realized and, in addition, waves of several types, previously unknown, were recorded. In 1953, the matched horizontal components were added and the expected advantages again were soon realized. During the next few years, additional instruments of this type were installed in Bermuda, Pietermaritzberg, Perth (Western Australia), and Waynesburg (Pennsylvania).

Excellent results having been obtained in all cases, it was decided to make available a standard design of this seismograph system. This design was engineered by Lehner and Griffith, Inc., and is being manufactured by them as the Press-Ewing seismograph system. These instruments have been recording in Pasadena since 1956 with $To = 30$ sec, $Tg = 90$ sec, pendulum and galvanometer being critically damped. They will be operated at a number of stations during the International Geophysical Year.

Description—Figures 1 and 2 are photographs of the vertical and horizontal components, respectively. The glass sphere on the vertical pendulum serves as the buoyancy compensator. The upright is made of Invar for the vertical and of brass for the horizontal components. It is bolted to the pier through clearance holes in the base plate. The transducer is of the moving coil type, with a coil of 5000 turns of 34-gage magnet wire with total resistance 500 ohms. The magnet is made of Alnico V alloy with pole pieces arranged to produce a radial magnetic field of 2000 gauss.

The brass boom is 14¼ inches long and the inertial mass is 15 lb. The pendulum period is adjustable for stable operation in the range 10 to 30 sec. Damping of the pendulum is accomplished by shunting the coil, approximately 3800 ohms being required for critical damping for operation at a pendulum period of 30 sec. Sensitivity is adequate even when operated in a highly overdamped condition. Space is available on the base plate for installing an additional transducer, for example, to drive a second galvanometer or, after suitable amplification, an ink recorder.

All structural elements of the horizontal pendulum have equal coefficients of thermal expansion, the upright and boom being brass, and the suspension wire phosphor bronze. The boom length, inertial mass, transducer, free period, damping, and sensitivity are identical with those of the vertical.

The cover for each instrument is fabricated from sheet aluminum with a plexiglass window. All joints are sealed against draft with felt gaskets.

A Lehner galvanometer with free period 90 sec, coil resistance 500 ohms, critical damping, current sensitivity 10^{-10} amperes per millimeter

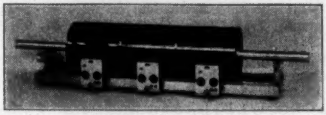

FIG. 3 – The triple component recording drum

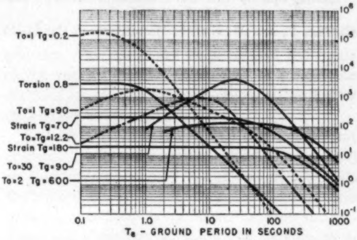

FIG. 4 – Calibration curves of various seismograph systems

deflection at one meter is connected to the transducer through a resistive network. The network provides for variation of damping and of sensitivity.

A triple drum recorder is used (Fig. 3), providing perfect alignment between the three seismograms, to facilitate comparisons of phases and determination of orbital motion.

The calibration curve of the instruments operating with pendulum and galvanometer at critical damping is shown in Figure 4. Also shown are curves for other seismographs currently in use. The method of calibration was essentially that of *Murphy* and others [1954].

The peak magnification of 4200 occurs for periods of 25 sec. The response diminishes rapidly for periods less than 25 sec and more gradually for longer periods. Owing to its superior magnification in the period range 20–200 sec, this instrument produces seismograms containing information previously unavailable.

Performance—Although primarily used for research, seismograms from this instrument have been surprisingly useful in routine analysis by providing clear recordings of later body phases, G waves, and the impulsive initiation of surface waves.

The recording of mantle Rayleigh waves from the great Kamchatka earthquake of November 4, 1952, made possible an extension of the dispersion curves for these waves as well as a determination of internal friction in the mantle [*Ewing and Press*, 1954].

Press and *Ewing* [1955] found clear indications of the new phases *Pa* and *Sa* on recordings of these seismographs. *Oliver* and *Ewing* [1957] reported on observations of unusually long-period microseisms.

These examples show how the new instruments have contributed to seismological research by providing increased sensitivity in a period range not covered by other seismographs.

Acknowledgment—That part of this research conducted in Pasadena was supported by a grant from the Alfred P. Sloan Foundation.

Shore-Based Recorder of Low-Frequency Ocean Waves*

FRANK E. SNODGRASS

Abstract—A pressure head on the sea bottom contains a hydraulic filter which attenuates high-frequency signals caused by ordinary gravity waves, and low-frequency signals caused by tides. Maximum response is for frequencies at about one cycle per 1000 sec. A strain-gage transducer converts the filtered pressure fluctuations into electrical signals, which are transmitted to shore through a cable.

Introduction—The instrument described in this paper was designed for the study of ocean waves whose frequency lies between those of the ordinary waves and those of the tides. Such low-frequency waves fall into two categories: (1) a low-frequency noise, which is always present and appears to be associated with meteorologic factors, and (2) tsunami waves, which arrive every year or two and are associated with earthquakes under the sea floor.

The existence of such low-frequency waves has long been known from ordinary tide-gage records, but these are not well adapted to record them, particularly the low-amplitude noise. In 1948 a pier-mounted gage with a three-stage hydraulic filter [*Munk*, *Iglesias* and *Folsom*, 1948] was installed at the end of Scripps Pier for the particular purpose of studying these waves. In 1952 a second instrument was installed at Oceanside Pier, 24 mi north of the Scripps instrument and connected to it by radio link. Subsequently a portable instrument for operation on remote islands was developed [*Van Dorn*, 1956] which employed a shore-based hydraulic filter connected to the sea by a tube or pipe. An instrument for offshore measurements from shipboard which employs a Vibrotron transducer and digital recording is discussed by *Snodgrass*, *Munk*, and *Tucker* [1958].

Description—Sea pressure is transmitted through a rubber bellows (Fig. 1 and 2). Two capillaries, R_1 and R_2, lead to two domes with metal bellows, C_1 and C_2. The rubber bellows, capillary tubing, and the compliant chambers between the dome and the outside of the metal bellows are filled with silicone fluid. The inside of the bellows and of the transducer chamber is filled with air maintained at atmospheric pressure. The total air reservoir is large relative to the bellows, and the variation in air pressure due to the deflection of the bellows is negligible compared to the changes in outside pressure. The transducer chamber and the inside of the bellows can be pressurized to extend the depth of installation, which is otherwise limited by the bellows to 10 m (one bar).

Two identical bellows are used in the compliant chambers, but the capillary tubes are adjusted so that their resistances to the flow of hydraulic fluid have a ratio of about four to one. A strain-gage pressure transducer is connected between the two compliant chambers to sense the differences in pressure. Because of the flow resistance of the capillary tubing, pressure fluctuations of very high frequency (ordinary waves) cause negligible pressure changes within the compliant chambers and between them. For pressure fluctuations of very low frequency (tides) the pressure in each chamber essentially equals the applied pressure, and the pressure difference between the chambers is again negligible. For intermediate frequencies the pressure in the two chambers is unequal owing to the difference in resistance of the capillary tubes, and an appreciable signal will be produced by the transducer.

Response characteristics—The equivalent electrical circuit of the pressure head is shown in Figure 2. Any arrangement of two resistors and two condensers to produce a band pass filter has a complex voltage attenuation of

$$e_0/e_i = A/(1 + jB) \tag{1}$$

For the particular arrangements shown in Figure 2, the constants have the values

$$A = (\beta - 1)/(\beta + 1) \tag{2}$$

$$B = \beta^{\frac{1}{2}} \, (k - 1/k)/(\beta + 1) \tag{3}$$

where

$$\beta = t_2/t_1 = R_2C_2/R_1C_1, \qquad t_2 > t_1 \tag{4}$$

$$k = f/f_0, \qquad f_0 = 1/2\pi\sqrt{t_1t_2} \tag{5}$$

t_1 and t_2 are the time constants associated with the circuit, f is the frequency of the applied signal, and

---

* Contribution from the Scripps Institution of Oceanography, New Series No. 977.

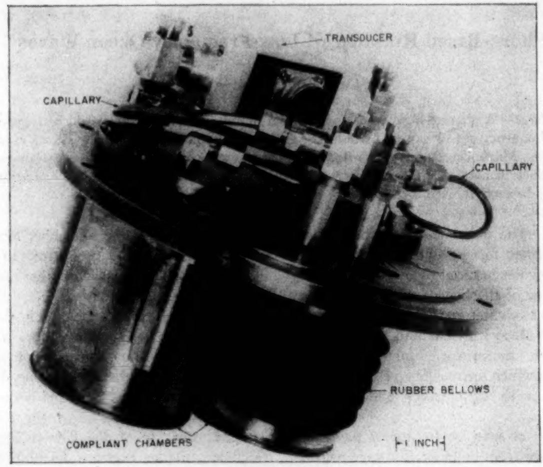

FIG. 1 – The pressure head assembly removed from its pressure case

f_0 is the center frequency of the filter. Thus the frequency response characteristics of this filter are described completely if the two time constants are known.

For a unit harmonic input, $\cos 2\pi ft$, the output can be written $r\cos(2\pi ft + \theta)$ where

$$r = \text{real part} \quad A/(1+jB) = A\cos\theta, \qquad \tan\theta = B \tag{6}$$

At the center frequency $k = 1$, $r = A$ and $\theta = 0$ (the output is in phase with the input). The half power points of the filter are at a frequency such that

$$k = (1/2\delta)[\sqrt{1+4\delta^2} \pm 1], \qquad \delta = \beta^{\frac{1}{2}}/(\beta+1) \tag{7}$$

The asymptotic behaviors are

$$r = Ak/\delta, \qquad \theta = 90^\circ \qquad \text{for } k \ll 1 \tag{8}$$

$$r = A/\delta k, \qquad \theta = -90^\circ \qquad \text{for } k \gg 1 \tag{9}$$

The frequency response curves in Figure 3 indicate results obtained using values of $\beta = 3.5$ and $f_0 = 1.37$ cycles/kilosec (730 sec/cycle). These values centered the filter in the low frequency band being studied and provided good attenuation of the signal produced by ordinary gravity waves and tides.

Calibration of the pressure head—The response of the pressure head is completely and conveniently described in terms of the two time constants, and relatively simple tests can be made to calibrate the pressure head. A step pressure input at time $t = 0$ (by suddenly lowering the pressure head through several inches of water) results in a transient response

$$x(t) = e^{-t/t_2} - e^{-t/t_1} \tag{10}$$

The time constants t_1 and t_2 can be determined from the measurements of the time t_m and the maximum amplitude x_m of the transient response

$$x_m = \frac{\beta - 1}{\beta}\beta^{-1/(\beta+1)}, \qquad t_m = t_2\frac{\ln\beta}{\beta - 1} \tag{11}$$

with $\beta = t_2/t_1$. The initial slope of the transient response curve

$$[dx/dt]_{t=0} = 1/t_1 - 1/t_2 = \ln\beta/t_m \tag{12}$$

can be used as a check.

Temperature effects—The principal temperature effect results from the linear dependence of the time constants, t_1 and t_2, on the viscosity of the oil. Results of calibrations at four temperatures are plotted in Figure 4. These data indicated that within the range of temperatures to which the instrument might be subjected, $\log t_1$ and $\log t_2$ decrease linearly with temperature; accordingly $\log f_0$ increases linearly with temperature. Since both time constants are affected proportionally,

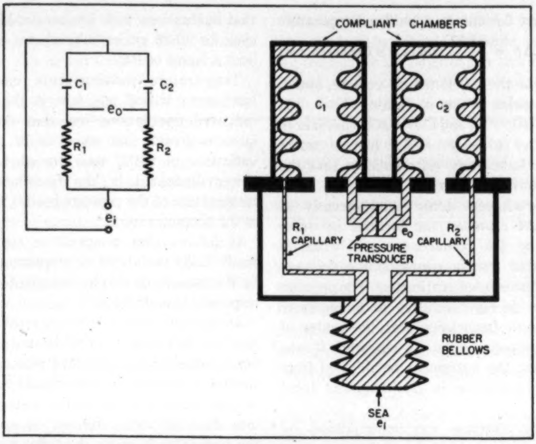

FIG. 2 – Schematic diagram of the hydraulic and equivalent electrical circuits of the pressure head; shaded region is oil-filled; remaining volume is filled with air

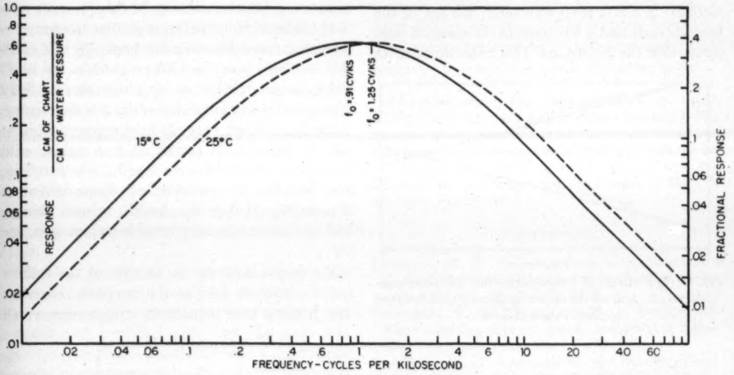

FIG. 3 – Amplitude response of the recorder; the right scale refers to the response r (Eq. 6) of the hydraulic filter; the left scale to the over-all response, including the electric components, which was used in obtaining the record shown on Fig. 5

the ratio of the time constants β is not affected. Thus the response curve (Fig. 3) is translated along the frequency axis. In our work it was necessary to allow for this effect in the interpretation of the instrument output, particularly at the high and low frequencies.

In addition to the problem involving the mean water temperature there are also output signals due to temperature transients. This effect arises on account of the differential expansion between the metal parts of the compliant chamber and the oil contained within these chambers, the oil expanding more rapidly than the metal container.

An estimate of the pressure change in the compliant chamber Δp due to a sudden temperature change ΔT is $\Delta p = \frac{\alpha V \Delta T}{C}$ where α is the coefficient of expansion of the oil, V the oil volume, and C the bellows spring constant. Setting $V = 100$ cm^3, $\alpha = 1.2 \cdot 10^{-3}$/°C, and $C = 0.036$ cm^3/(cm of water pressure) gives $p = 3.3$ (cm of water pressure)/°C. Laboratory tests indicate that the effect is somewhat smaller.

Since these changes occur simultaneously in both compliant chambers, an increase in water temperature by 1°C produces a signal which is indistinguishable from a corresponding decrease of water pressure of a few centimeters. The pressure head therefore is most sensitive to temperature fluctuations with frequencies near the center of the pressure response curve. In our work it was imperative that the instrument be shielded from temperature fluctuations in the frequency band of interest.

Temperature shielding was accomplished by burying the pressure head in the sand bottom to a depth of about one foot. If the test site did not have a suitable sand area, the pressure head was installed in a box filled with sand; the size of the box was such that a minimum of six inches of sand surrounded the instrument. This insulation assures that fluctuations with frequencies higher than one cycle/hr (0.28 cycles/kilosec) are reduced by at least a factor of 100.

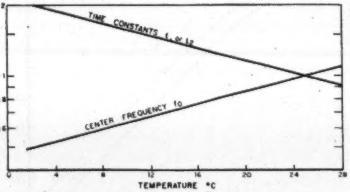

FIG. 4 – The effect of temperature on the time constants t_1, t_2, and on the center frequency f_0 all referred to their values at 25°C

Temperature measurements made with the instrument buried one foot in the sand bottom indicated fluctuations less than 0.01°C for frequencies greater than one cycle/hr, although daily variations of 0.5°C were recorded. The electric power dissipated in the transducer raised the temperature of the pressure head 0.5°C above that of the bottom water.

It follows that temperature signals are very small. Daily variations of temperature and heating by the transducer also have negligible effect on the response characteristics.

Mechanical features—In order that the pressure head can be buried in sand the unit is encased in a brass container and provided with a snorkel. The snorkel, a $\frac{1}{4}$-inch pipe, is shielded by an outer tube so that suspended material in water cannot settle into the instrument. Silicone oil was selected for the hydraulic fluid for the following reasons: (1) the oil is chemically inert and has excellent electrical properties which permit its use in the transducer, (2) the viscosity of the oil varies relatively little with temperature so that the temperature effects on calibration are small, (3) it is available at high viscosities (500 centistokes was used) which permit the use of large diameter capillary tubing and so minimize difficulties due to plugging.

Capillary tubes were made of copper tubing as follows: (1) 15-inch length, $\frac{3}{16}$-inch tubing with 0.125-inch ID, (2) $4\frac{3}{4}$-inch length, $\frac{1}{8}$-inch tubing, 0.062-inch ID. The metal bellows dimensions were: $2\frac{3}{8}$-inch OD, $2\frac{7}{8}$-inch live length, volume change, 2.25 in^3/bar; maximum allowable compression, one bar.

The space between the outside of the bellows and the dome is used as the compliant chamber. The bellows then remain in compression at all

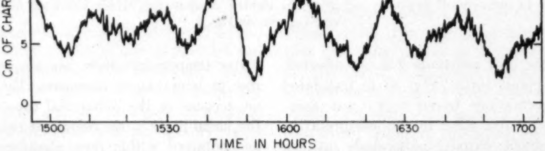

FIG. 5 – Sample wave record; vertical scale is in chart centimeters corresponding to the calibration curve, Fig. 3; the record, which is unusually active, was taken on Feb. 23, 1956, off Camp Pendleton, Oceanside, California

times and provide a nearly uniform spring constant. The arrangement permits the use of a small oil volume, and this in turn reduces temperature signals.

An important design consideration is that no air pockets should remain in the oil-filled portion of the instrument. The gage is filled with hydraulic fluid by removing the four pipe plugs in the hydraulic tubing (see Fig. 1) and connecting a reservoir of oil to these points. The unit then is installed in the brass housing and evacuated with a pump. Air contained in the complaint chamber, transducer, capillaries, etc., is drawn out. When atmospheric pressure is reapplied, the unit fills with oil. Any remaining air bubbles are absorbed by the fluid since most of the air normally in solution has been removed.

Electrical features—The pressure transducer must withstand many meters of water pressure during installation, yet be capable of sensing a millimeter of water pressure after reaching equilibrium on the bottom. A strain-gage transducer rated at 1.0 psi differential can withstand ±10 psi differential; the gage therefore can be lowered suddenly through 13.7 m of water without damage to the transducer. Equipped with a 2000-ohm, 31 v strain-gage element, it has a conversion factor of 0.9 mv/(cm water pressure) over its ±1 psi differential operating range. By connecting the gage output directly to a standard, self-balancing-potentiometer recorder, such as a Speedomax, overall recording sensitivities of the order of one centimeter of chart per centimeter of water pressure are readily obtained. Equivalent sensitivities were obtained without difficulty using d-c amplifiers and recording milliammeters, such as the Esterline-Angus.

Electrical power (30 v at 15 milliamp) was supplied to the gage from an electronically regulated power supply whenever 110-v a c power was available. At remote beach sites the gage was operated from wet cell batteries with a Speedomax recorder being driven by a 28-v d c to 110-v a c, 60-cycle converter. Thirty hours of operation could be obtained from four 6-v automobile batteries. Operating time can be greatly increased by using transistor amplifiers and spring-driven chart recorders.

Four-conductor cable is required for the bridge-type strain-gage transducer, while an additional two conductors are required if a thermistor circuit is used to indicate temperature of the pressure head. Cable lengths of several miles can be used providing leakage resistance between leads and between the cable and earth does not drop below about 0.1 megohm. Below these resistances the shunting effects or voltages generated due to sea water leakage may affect the readings.

Results—Several gages using the design described in this report have been used for three years with good results. Figure 5 shows an unusually active record. Ordinary gravity waves of 12-sec period (80 cycles/kilosec) are recorded with a response factor of 0.02 (chart cm)/(cm water pressure). These waves are responsible for the thickness of the trace. On the original record individual waves can barely be identified. For surf beat in the period band 1 to 4 minutes (4 to 16 cycles/kilosec) the response factor is between about 0.3 and 0.1. Twenty-minute-surges (0.83 cycles/kilosec) have a factor of 0.62. The tide, being reduced to 0.04 of its amplitude, is indicated as a slight drift in the record. The features here indicated can be resolved by a frequency analysis. A discussion will be given in a forthcoming paper.

Acknowledgments—The author wishes to thank Walter Munk for many helpful suggestions and Frank Peterson for his assistance in laboratory and field tests. Offshore Recording of Low-Frequency Ocean Waves*

F. SNODGRASS, W. MUNK, AND M. J. TUCKER

Abstract—A Vibrotron transducer on the sea bottom converts pressure into frequency of a stretched wire. The oscillations are counted and recorded on shipboard in a form suitable for subsequent filtering and spectrum analysis by high speed digital computers. Oscillation by 1 mm of water pressure in the frequency range 0.2 to 100 cycles/kilosec (periods 5000 to 10 sec) have been recorded at depths exceeding 100 m.

Introduction—In the introduction to *Snodgrass* [1958] a brief account is given of the installation of pier-based tsunami recorders along the California Coast. In a sense these shore installations have been a disappointment. Tsunami waves appear to be so well reflected by the continental slope that relatively little wave energy reaches the shore installations. The result is that tsunamis are better recorded by the standard tide gage at Honolulu than by the special instruments along the California Coast.

The instruments did, however, provide interesting information about the day-by-day low-frequency noise, with the suggestion that this noise was in the form of edge waves traveling up and down the continental shelf and borderland. The principal characteristic of edge waves is that their amplitude diminishes rapidly seaward. To test this hypothesis the present instrument was built, and simultaneous measurements were made onshore [see *Snodgrass*, 1958] and offshore. The hypothesis was subsequently confirmed [*Munk, Snodgrass*, and *Carrier*, 1956]. By now more than 30 offshore stations have been occupied. The instrument promises to be useful also for the deep-sea recording of tides.

Our requirements are that the instrument should be capable of measuring waves with an amplitude of a few millimeters in the frequency range 0.1 to 10 cycles/kilosec, at depths exceeding 100 m. We first attempted to design a differential pressure gage, using air or springs as the compliant element. In the case of the air volume the instrument turned out to be a far better thermometer than a pressure transducer; the latter case called for special development of springs. A solution which easily met the above requirements turned out (perhaps surprisingly) to be an absolute pressure gage, using a Vibrotron pressure transducer, which converts pressure to frequency.

Pressure transducer—The Vibrotron pressure transducer [*Poindexter*, 1952; *Ohman*, 1955; *Prast* and others, 1955] was originally developed by the Southwest Research Institute, and is now being produced by B.-J. Electronics, Borg-Warner Corporation, Santa Ana, California. A pressure signal varies the frequency of a wire vibrating in a magnetic field. The induced voltage can be transmitted, recorded, or analyzed with all the advantages normally attributed to frequency modulated systems.

The vibrating wire is made of tungsten; the diameter is 0.025 mm and the length about 6 mm. It is stretched between the rigid structure and a small diaphragm exposed to pressure. The wire and its support is encased in an evacuated 2-cm dia cylinder 9 cm long, with electrical connections at one end, the diaphragm and pressure port at the other (Fig. 1). The wire is under tension of 15,000 to 20,000 bars. Increasing the pressure applied at the pressure port deflects the diaphragm inward, diminishes the tension, and decreases the natural frequency of the wire.

The wire vibrates in a magnetic field provided by Alnico V magnets with a field strength of 5,000 to 10,000 gauss and a gap of about 0.25 mm. This vibrating wire and a second, non-vibrating wire are connected in a bridge which is approximately balanced for d c. The output of the bridge, which is essentially the a c voltage induced in the vibrating wire, is amplified and fed back to the bridge in the sense required to maintain the wire in oscillation. The amplifier provides also for a sufficient power output (10 v across 100,000 ohms) to drive recorders or analyzers. Step-down transformers are used to match the output to low-impedance cables.

Transistor amplifiers—A thermionic amplifier matched to the Vibrotron transducer is available from the manufacturer, but this unit is not practical when power is supplied through long high-resistance cables. A transistorized amplifier was used which required only 4 ma at 20-v d c.

The amplifier circuit shown in Figure 2 (based

---

* Contribution from the Scripps Institution of Oceanography, New Series No. 978.

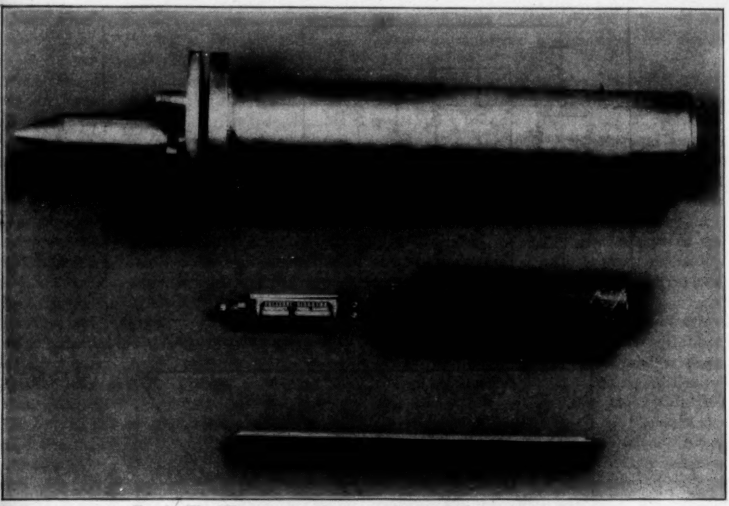

FIG. 1 – The Vibrotron transducer, transistor amplifier, and pressure case

on a development by *Snodgrass* and *Cawley* [1956]) has a gain of about 20,000 with an output of about 6 v. The resistance of the vibrating wire is low compared to the emitter load resistance, so that the Vibrotron can be connected directly to the first transistor amplifier. The second transistor acts as an impedance converter to reduce phase shifts resulting from the cut-off effect and the shunt input capacitance of the following transistor. The reduced phase shift of the amplifier, measured with the feedback condenser removed, is of the order of 60° and needs to be reduced still farther. The feedback condenser for each amplifier is adjusted by trial and error to produce zero phase shift at about 12 kc. The phase shift over the entire band 10 to 17 kc is then acceptable.

The complete system must have considerable frequency stability, since frequency is measured to one part in 10^6. This stability requires a constant amplitude of vibration of the wire. Effective amplitude control was accomplished by allowing the amplifier to overdrive in its last stage. The resulting distortion in the output wave form is not troublesome inasmuch as the recorded values depend only on zero axis crossings.

The amplifier was built as a potted plug-in unit with a diameter 3.8 cm and an overall length of 12.7 cm (Fig. 1).

Pressure sensitivity—We used two types of transducer, with the following characteristics:

Transducer	Pressure range		Frequency
	m	lb/in^2 abs	cycles/sec
Deep	0–750	0–1100	17,500–10,000
Shallow	0–180	0–250	17,500–10,000

A typical calibration for the shallow transducer is shown in Figure 3. The straight line is fitted to the equations $f^2 = -AP + B$ for $A = 1.26$ (kc/sec)^2/(m of water pressure) and $B = 317$ (kc/sec)^2. The pressure sensitivity $df/dP = -A/2f$ varies from 0.36 (cycles/sec)/(cm of water pressure) at zero absolute pressure to 0.64 (cycles/sec)/(cm of water pressure) at absolute pressure of 180 m of water (depth = 170 m).

Temperature sensitivity—The mechanical structure of the vibrating wire element is designed to minimize differential thermal expansion between the vibrating wire and the support structure for the wire. The manufacturer guarantees a temperature sensitivity of not more than 0.05 pct of the band width per degree Fahrenheit. For a transducer with a frequency band of 10,000 to 17,500 cycles/sec, the maximum response to temperature change by 1°C is then $0.0005 \times 7500 \times 1.8 = 6.75$ cycles/sec, which is equivalent to $6.75/0.36 =$

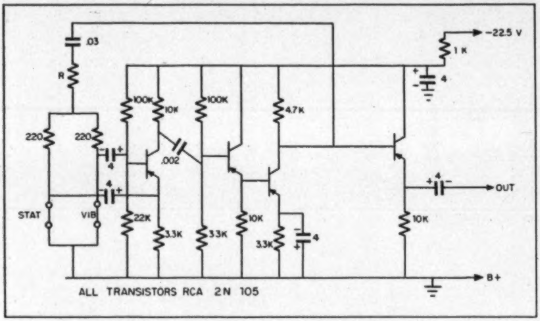

FIG. 2 – Schematic diagram of the Vibrotron transistorized amplifier

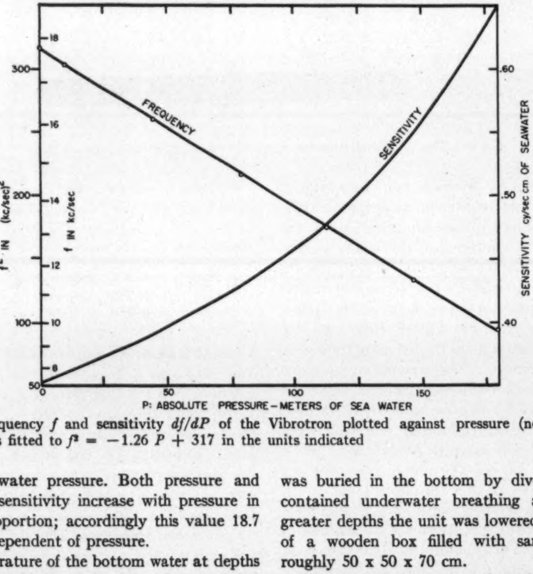

FIG. 3 – Frequency f and sensitivity df/dP of the Vibrotron plotted against pressure (not depth); the straight line is fitted to $f^2 = -1.26\ P + 317$ in the units indicated

18.7 cm of water pressure. Both pressure and temperature sensitivity increase with pressure in the same proportion; accordingly this value 18.7 cm/°C is independent of pressure.

The temperature of the bottom water at depths of several hundred meters may change rather suddenly by large fractions of a degree. In order for temperature 'noise' to be less than 1 mm of water pressure it is necessary that the temperature fluctuations of the Vibrotron transducer be less than that of the water by a factor of 100 for the frequency range of interest. This result was achieved by insulating the unit with moist sand. In water depths of less than 40 m the instrument was buried in the bottom by divers using self-contained underwater breathing apparatus. At greater depths the unit was lowered in the center of a wooden box filled with sand, measuring roughly 50 x 50 x 70 cm.

The theoretical response of a cylindrical box of compatible dimensions and filled with water (the role of the sand is to prevent convective heat transfer) indicates a reduction by a factor of 100 for a frequency of one cycle per hour (0.36 cycles/kilosec), by a larger factor at higher frequencies. The result was confirmed by comparing computed and measured response to a step change in temperature. In the laboratory the sand-insulated

Vibrotron was submerged in an ice bath, and at sea into the cold bottom water. Roughly 12 hr are required to reach equilibrium temperature (Fig. 4). In the case of tide measurement, the daily temperature variation of the Vibrotron had to be allowed for.

Stability—Various tests were performed with the Vibrotron and transistorized amplifier. A change of battery voltage from 22 v to 18 v altered the frequency by 0.1 cycles/sec. A change in the amplifier temperature from 25°C to 43°C decreased the frequency by 1.5 cycle/sec. Connecting a 1.0 mfd capacitor across the output transformer secondary (to simulate a long cable) decreased the frequency by 0.7 cycle/sec. A test of the over-all stability under ordinary working conditions is discussed under the heading *Noise spectrum*.

Digital recording—The pressure fluctuations of greatest interest in the present work have frequencies between 0.3 and 3 cycles/kilosec (periods between five minutes to one hour) and amplitudes of a few millimeters. Since the Vibrotron is an absolute pressure device, its output contains tides and ordinary waves, and these components are several hundred times the amplitude of the required signals. In the case of the shore-based recorder [see *Snodgrass*, 1958] the filtering of tides and ordinary waves is done pneumatically. Electronic filters were found to be unreliable at such low frequencies, but they were useful for monitoring the equipment during the tests. Our solution is to filter by numerical methods using high speed digital computers. Fortunately the output of the Vibrotron transducer is convenient for digital recording.

Commercial devices are available which count the number of cycles in a given time, using a quartz crystal clock to control the counting interval. This appears to be the most straight-forward and reliable means of recording. A Berkeley Scientific EPUT (events per unit time) meter equipped with a scanning and printing unit was used to tabulate the data on an adding machine tape. The timing interval can be selected as any multiple of one second up to 60 sec and is stable to one part in 10^6. A one-second time interval for the printing interval is also controlled by the crystal clock.

As an example, consider conditions summarized in the first line of Table 1. The shallow Vibrotron is very near the surface (absolute pressure about 10 m of sea water), and the oscillations are counted over a one-second interval. The sensitivity is 0.36 (cycles/sec)/cm water pressure, and hence a difference in count by one unit (say from 17,300 to 17,299) corresponds to 2.78 cm of water pressure. The last digit is in doubt, and hence this pressure equivalent of the EPUT least count is a measure of uncertainty.

The low precision is the result of dealing only with an integral number of cycles during a short time interval. There are two remedies. One is to deal with units smaller than entire cycles, such as half cycles, or third cycles, and this can be accomplished by multiplying Vibrotron frequency by

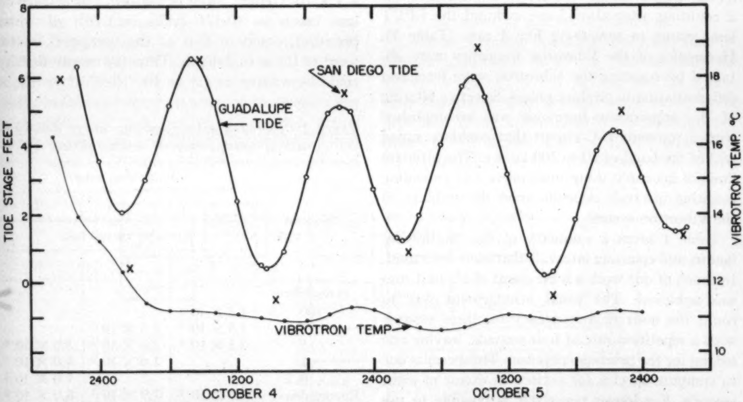

FIG. 4 – Tide and temperature data obtained at Isla de Guadalupe; gage installation depth 115 m; open circle points represent 5-min averages of uncorrected Vibrotron data; the measured Guadalupe tides were lower in amplitude and occurred earlier than predicted San Diego tides

				1	59	0.12

[a] Cycles per second per centimeter of water pressure

two or three, and counting the mutliplied frequency. The other remedy is to count over intervals of time longer than one second. It is advantageous to do both; that is, multiply the Vibrotron frequency and count for several seconds.

The frequency of modulation and its amplitude (again in units of frequency) are both exceedingly small compared to the carrier frequency. Under these circumstances the multiplying factor is limited by the electronic counters. The equipment used has a maximum counting rate of 100 kc/sec. The multiplying factors used vary from 5 at shallow depths (Vibrotron frequency 17.3 kc/sec; EPUT frequency 5 × 17.3 = 86.5 kc/sec) to 10 near maximum depth (Vibrotron frequency 9.6 kc/sec; EPUT frequency 10 × 9.6 = 96 kc/sec). These multiplication factors, in conjunction with a counting interval of 3 sec, reduced the EPUT least count to something like 1 mm (Table 1). Harmonics of the Vibrotron frequency were obtained by squaring the Vibrotron wave form and differentiating to produce pulses. Selective filtering of the appropriate harmonic was accomplished with a resonant L-C circuit that could be tuned within the band of 80 to 100 kc/sec. The ultimate limit of accuracy using multipliers and extending counting intervals depends upon the stability of the Vibrotron system.

Table 1 gives a summary of the multiplying factors and counting intervals that have been used. In much of our work a least count of about 1 mm was achieved. The usual arrangement was to count the multiplied frequency for three seconds with a repetition rate of four seconds, leaving one second for the printing operation. This permits one to compute spectra for periods in excess of eight seconds. For longer periods it is possible to use longer counting periods, but this introduces the aliasing problem; if there is an appreciable signal component near the sampling frequency, the difference frequency will appear as a spurious low-frequency component. In our work this is a serious problem, because the low-frequency waves are so much smaller than the ordinary waves present. The safest procedure is to maintain the sampling frequency sufficiently high so that the bottom pressure fluctuations induced by waves of that frequency are essentially eliminated at the depth of the instrument [for further details see *Munk, Snodgrass*, and *Tucker*, in press]. For measurements of tides, and of the mean absolute depth, very long counting times are entirely appropriate.

The noise spectrum—There is no single number expressing the stability of the instrument. It depends upon the frequency under consideration. A convenient presentation is the energy (or power) spectrum of noise level. This was obtained by analyzing the output of a Vibrotron with a capped pressure port using just the same methods as for the actual wave measurements [*Munk, Snodgrass*, and *Tucker*, in press]. For temperature protection the capped Vibrotron and transistor amplifier were buried 120 cm in the sand bottom at a water depth of 8 m.

The result of three spectra is summarized in Table 2. The noise record from the capped instrument is interpreted in terms of equivalent pressure fluctuations on an uncapped instrument. The first line states that the contribution to the mean square pressure deviation of the record from the frequency band 99.5 to 100.5 cycles/kilosec equals 1.3×10^{-4} (cm of water pressure)^2. The sensitivity was taken as (0.372 cycles/sec)/(cm of water pressure), equal to that of the uncapped instrument at the actual depth. Thus the energy density could be written as $1.3 \times 10^{-4}\ (0.372)^2 = 1.8 \times$

TABLE 2 – *Vibrotron noise spectrum; energy density in (cm of water pressure)^2/(cycles/kilosec)*

Frequency	Multiplying factor 4	Multiplying factor 4	Multiplying factor 1
	Counting interval (sec) 3	Counting interval (sec) 14	Counting interval (sec) 60
cycles/kilosec			
100	1.3×10^{-4}		
25	1.5×10^{-4}	1.5×10^{-5}	
5	2.5×10^{-4}	2.3×10^{-5}	5.0×10^{-5}
1		1.6×10^{-4}	4.0×10^{-5}
0.2			1.0×10^{-3}
Energy density from least count	0.9×10^{-4}	1.9×10^{-5}	6.0×10^{-6}

10^{-5} (cycles/sec)^2/(cycles/kilosec), or 0.018 (cycles/sec)^2/(cycles/sec).

The last line gives the energy density of a white noise generated by a random variation of $\pm\frac{1}{2}$ count of the last recorded digit. For each test the high-frequency noise was at roughly this level, and thus the accuracy was limited by the EPUT counting rate (10^5 cycles/sec) rather than by the Vibrotron. (At high frequencies better results are obtained by reading off values from a continuous line record; see next section.)

In each of the three spectra the values rise for low frequencies. There is some evidence that this is due to temperature effects on the EPUT crystal. Thus within the range of frequencies covered by the noise spectra (periods 10 to 5000 sec) the present limitations appear to be imposed by the recording equipment rather than the transducer. But it must be emphasized that the over-all stability of the system is well within the exacting limits required by our work.

In addition there is a steady drift of frequencies which cannot be attributed to the recording system. This drift does not contribute appreciably to the frequencies covered by the noise spectra. The Vibrotron frequency increased by 0.37 (cycles/sec)/day (-1 cm of equivalent water pressure per day) at the beginning of a continuous 25-day test period. This drift rate diminished gradually and at the end of the test period was about two-thirds the initial rate.

Continuous line recording—A graphical record is very useful for monitoring while the test is underway. The graphical records were not used for analysis except at frequencies above 125 cycles/kilosec (periods less than 8 sec). At these high frequencies the electrical equipment is relatively stable and the limitation of the least count is avoided. In fact, we have recorded actual energy levels as low as 10^{-6} cm^2/(cycles/kilosec) at a frequency of 200 cycles/kilosec (period 5 sec) with the Vibrotron at 115-m depth off Guadalupe, using values read off the continuous Speedomax record.

The arrangement is indicated by the block diagram (Fig. 5). The multiplied frequency of the Vibrotron was heterodyned with a crystal oscillator, and the difference frequency converted to a voltage by a Hewlett Packard frequency meter. The voltage was filtered through a series of RC-circuits of very long time constant, and recorded on a multichannel Speedomax recorder.

The crystal oscillator unit was designed to provide an output signal that could be adjusted throughout the band of 80 to 100 kc/sec. This adjustment was accomplished by heterodyning dual temperature-controlled crystal oscillators operating near 5 mc/sec to produce a difference frequency within this band. Each of the oscillators was provided with ten crystals. The crystals of the first oscillator were cut at 2000 cycles/sec intervals, the crystals of the second oscillator cut at 200 cycles/sec intervals. The 100 combinations provided frequencies spaced at 200 cycles/sec. By means of a small variable condenser connected across the crystal in one oscillator it was possible to tune the difference frequencies by about ±200 cycles/sec so that any desired frequency could be obtained within the frequency band of 80 to 100 kc/sec.

The Hewlett Packard frequency meter provided an output of 1 ma in a 1300-ohm load resistance, or 1.3 v, for full scale reading. Thus on a 0 to 500-cycle band the conversion factor would be 1.3 v/500 cycles/sec or 2.6 mv/(cycles/sec).

Consider a typical operating condition. The Vibrotron is installed in 115 m (125 m abs); the average frequency is 12.7 kc/sec, and the Vibrotron sensitivity 0.50 (cycles/sec)/(cm of water pressure). Using a multiplier of 7, the frequency becomes 88.9 kc/sec and the EPUT sensitivity 3.5 (cycles/sec)/(cm of water pressure). A crystal

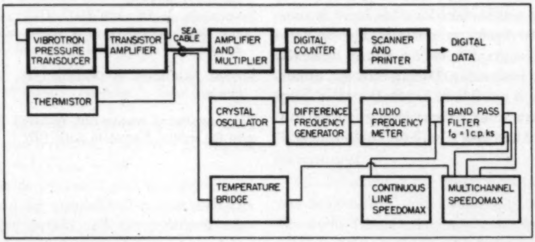

FIG. 5 – Block diagram of the low-frequency wave-recording system

oscillator frequency of 88.7 kc/sec provides a difference frequency of 200 cycles/sec. On a 0 to 500-cycles/sec band of the frequency meter, the average voltage is 200 × 2.6 = 520 mv, and the sensitivity 2.6 × 3.5 = 9.1 mv/(cm of water pressure). These values are reduced to 52 mv and 0.91 mv/cm respectively by using a 10/1 step-down attenuator. Now by recording on a 10-mv range Speedomax with a 0 to 100-mv biasing control, chart sensitivities 2.5 (chart cm)/(cm of water pressure) are obtained.

Rapid drifting due to tides and large fluctuations due to ordinary gravity waves are suppressed by means of band pass filters using biased electrolytic condensers. The condensers must be insulated against large temperature changes. Their leakage must be taken into account when evaluating the filter response. The condensers also exhibit a hysteresis effect (sometimes referred to as soaking). For the present purpose of obtaining qualitative results, the electrolytic condensers provide a simple and adequate means of obtaining the long-time constants.

Installations—The Vibrotron is placed on the sea bottom and connected with electric cables to the recording equipment. Cables up to three miles long have been used to connect the instrument to shore recorders.

There has been no entirely satisfactory solution for the case of shipboard recording. The instrument must not be disturbed by even one millimeter if the recording is to be of any use. One method is to employ the electric cable for an anchoring line. The Vibrotron is attached to a one-ton concrete weight. A second one-ton weight, separated from the Vibrotron by about 300 m of slack wire along the bottom, is intended to take the strain. For depths less than 150 m this arrangement has been satisfactory in reasonable weather. But in greater depths the ship motion resulted in a vibration of the cable which was transmitted to the instrument. In our early work we used 1500 m of 48 mm-dia armored cable and anchored a cable layer (a converted LCU) in depths up to 600 m. The development of an Amergraph cable 8.6 mm in diameter with a double reverse-lay 3175 kg-strength armor has now made it possible to handle the cable from a small research vessel. About 150 kg is added to the instrument and 100 m of 2-cm chain is lashed to the cable for holding power. An additional 15 m of 2-cm chain is lashed to the cable at mid-depth to provide spring anchor and to suppress cable vibration. Successful installations have been made in water depths up to 150 m.

For water depths of less than 150 m another method has worked out satisfactorily. The instrument was set on the bottom at a distance of about 500 m from the ship with the electrical cable floated across the surface. The section of cable between the surface and the bottom was kept taut by means of chain weights and submerged buoys. The ship was anchored by a conventional bow anchor, and could swing about her anchors without tangling the electrical cable and anchor wire.

For depths exceeding 150 m we now plan to try a third method. A taut electric cable is to be connected to a surface buoy, from which the signal is to be transmitted to the ship by radio link.

Acknowledgments—Frank Peterson has been very helpful on all stages of the development of this instrument. This paper represents results of research carried out by the University of California under contract with the Office of Naval Research and the Bureau of Ships of the Navy Department.

A Fluid Level Sensing Device of Simple Design

REINHOLD GERHARZ

Abstract—A liquid-filled section of a coaxial conductor is used as a level sensing element, which changes the repetition frequency of a unidirectionally recycling electromagnetic pulse by subjecting it to various transit times. The deviations of the frequency are measured and provide a criterion for the height of the column of liquid in the sensing section of the feedback circuit. The device was tested with tap-water, acetone, and carbon tetrachloride.

Modern telemetering is characterized by the reproducible reduction of physical values into multiple analogues of electromagnetic constants. Among the numerous systems that find application in technology, only a few devices are in use in which the measured analogue values are disclosed as a variable frequency. With a recently described signal generator [*Gerharz*, 1956], the signal repetition frequency of which is the principal carrier of information, a very suitable application has been found for the sensing of fluid levels.

The main features of this generator are presented in Figure 1. The signal repetition frequency is primarily determined by the transit time of electrons in the amplifier tube (a type EFP 60 electron valve) and the propagation time of electromagnetic signals in the loop of the coaxial feedback conductor. With a one-tube circuit and various conductor lengths, a frequency interval from 2×10^6 to 5×10^7 cps has been covered.

It appears evident from Figure 1, that a coaxial conductor of a fixed length but with a variable impedance also will cause a change of the signal repetition frequency and that this frequency change is a function of the variable impedance. The experimental arrangement has utilized a column of tap water as a medium of variable impedance. This was accomplished by permitting the water to rise in the interior of a specially prepared section of the feedback conductor, thereby causing a change of the signal propagation time through the gage section. More explicitly, the time required for one signal to travel across the entire loop will then become

$$T_{\text{total}} = T_{\text{tube}} + T_{\text{conductor}} + T_{\text{gage}}$$

and with T_{gage} varying as a function of the fluid level h, the signal repetition frequency f_r will be described by $f_r = 1/T_{\text{total}} = f(h)$.

To insure stable operation and to suppress reflections, caused by mismatched connections between the gage section and the feedback conductor, it was found adventageous, to connect the inner conductor of the gage directly to the signal output of the generator. The voltage output in the case of the illustrated circuit was about five volts negative.

The gage resembles essentially a concentric system of two metallic cylinders of different diameters. The inner conductor is an insulated copper wire of about three mm diameter connected to the cathode of the amplifier tube, while the outer cylinder is a length of brass tubing of 12 mm in diameter at ground potential. The length of the gage section is about 150 cm. Both conductors are enclosed and mounted in a tube of glass, which communicates with the reservoir, the level of which is to be measured. Form and length of the gage section are not critical as long as it resembles electronically a coaxial system of medium attenuation.

In another device, a *U*-bent glass tube has been used, the outside of which was covered with silver paint. The inner conductor again was a thin copper wire drawn through the tube. Small vertical slits scraped into the silver coating provided visual access to the inside fluid level. The total length of the tube was about two meters. This construction also permits the determination of refractive indices of fluids and level metering of substances of high electric conductance [*Gerharz*, 1957]. The glass tube serves as insulator and container of the liquid.

In operation, the amplifier tube sends a sequence of very short pulses through the gage and the rest of the coaxial feedback cable. The pulse repetition frequency is determined by the only variable in the otherwise stable system: the fluid level in the interior of the gage. For precise measurements special efforts become necessary to stabilize the tube voltage and to screen the circuit effectively from undesired influence of heat and from electrical disturbances.

The detection of the pulse repetition frequency was accomplished with an ordinary radio receiver. The useful telemetering bandwidth depends on the total length of the feedback cable and on the

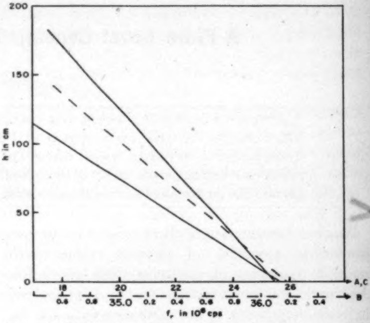

FIG. 2 – Calibration of a fluid-level telemeter with three metered substances; A, water; B, carbon tetrachloride; C, acetone

height of the gage. The emitted scattered field of the recycling signals is still large enough to be detectable some distance away from the device, even from well-shielded generators. Under the conditions leading to the representation of Figure 2, which shows relationship of the pulse frequency to the liquid level of three different fluids, a low quality short-wave receiver was still detecting the scattered signal at some 20 *m* distance from the gage. The range increased several fold in an open area after coupling a short antenna wire to the dynode of the amplifier tube.

Practical field applications for precipitation metering and for river- and well-level gages, however, would be operated more suitably, if the signal generator could pulse-modulate the amplitude of a small UHF-transmitter on a fixed carrier frequency. This would assist the control of several widely scattered automatically transmitting gage stations.

J. R. Philip (C.S.I.R.O. Division of Plant Industry, Deniliquin, N.S.W., Australia)—A rather complete mathematical physical method of studying problems of soil water movement is available and is capable of application to Hall's problem. I refer to the 'diffusion' approach, first suggested in concentration-dependent form by *Childs* and *George* [1948], used by *Klute* [1952] and later elaborated by the discusser [*Philip*, 1954b, 1955]. This is able to supply an integrated analysis of many isothermal soil-water problems [*Philip*, 1957e]. It involves numerical solution of a concentration-dependent diffusion equation which includes (in cases where gravity is important) an additional first order term. The problem of one-dimensional infiltraton in a uniform soil has been investigated in some detail. A brief account was given in *Philip* [1954b], and the work has recently received fuller publication [*Philip*, 1957abcd].

This is not to imply that there is no scope for an approximate analysis which may be much simpler and still represent the physical realities well enough to be useful for some purposes. A simple model which corresponds well to the experimental data of *Bodman* and *Colman* [1943], *Miller* and *Richard* [1952] and other workers has, in fact, been proposed by the discusser [*Philip* 1954a] and used by *van Duin* [1955] and *Hansen* [1955]. As presented, this simple analysis does not explicitly give the depth of the saturation surface as a function of time, but it is a straight-forward matter to deduce this for any particular numerical example. The relationship between this simple model and the more detailed 'diffusion' analysis is investigated in *Philip* [1957d].

Hall describes his hypotheses as 'restrictive'. In the discusser's opinion, the assumption that the hydraulic gradient in the 'transmission zone' is unity is entirely unreal. The data of Bodman and Colman, and of Miller and Richard reveal very large deviations from unit hydraulic gradient in the transmission zone. The magnitude of the deviations is shown by the following values of transmission-zone hydraulic gradients extracted from the experimental data of Miller and Richard. They are for ten minutes after infiltration began, except the Yolo loam, which is for 150 minutes: Yolo loam, 10; Tanbark sandy loam, 9; silica flour, 9; Hesperia sandy loam, 6. (Note that the arbitrariness of the bottom of the transmission zone and the fact that gradients were measured directly on the figures in the published paper lead to possible errors up to 20 pct in these values.) Bodman and Colman state that the decrease in infiltration rate with time appears to be due to "a decrease in moisture potential gradients resulting primarily from an increasing depth of penetration, that is to say, a vertical elongation of the transmitting zone." Hall, essentially, takes this gradient as zero from $t = 0$ onward and thus excludes from his model a vital aspect of infiltration dynamics. Detailed analysis [*Philip* 1957abc] bears this out and demonstrates that the assumption of unit hydraulic gradient would be acceptable only when t is so great that the infiltration rate has become sensibly constant.

Hall's equations (6) and (7) depend on the equality of K and K_t. However, experiment and physical reasoning indicate that if $K = K_t$, $\theta_s = \theta_t$, so that the terms under the square root signs of (6) and (7) are infinite and zero respectively. It might perhaps be argued that the equality of K and K_t should not be taken too literally, that K is essentially a parameter representing permeability in both zones and $(\theta_s - \theta_t)$ a second parameter representing the difference in storage capacity of the two zones. Even conceding this, we find that (7) gives the value $f = K$ (that is, a constant infiltration rate) for all $t > 0$ in the case, common in nature, when d is effectively zero. This paradox is inherent in Hall's use for all t of the long-time approximation that the hydraulic gradient in the transmission zone is unity. Incidentally, putting (1) in (4), setting $\Delta z/\Delta t$ equal to dz/dt, integrating for $K \neq K_t$ and using the condition $z = 0$ at $t = 0$ gives the following, which should replace (5) of the paper

$$\frac{z}{K - K_t} - \frac{Kd}{(K - K_t)^2} \times \log\left[1 + \frac{(K - K_t)z}{Kd}\right] = \frac{t}{\theta_s - \theta_t} \qquad (8)$$

A number of points arise in connection with Hall's relation of his experiments to his analysis:

(1) One must suppose that the legend of Figure 1 is in error, since (6) would give information about z, the depth of penetration of the saturation surface, not "the position of the wetting front."

(2) Further information about the experiments would be useful; for example, what was the value of d? (Applying (6) to the "calculated" line of Fig. 1, discusser deduces $d \approx 28$ cm.) How was the position of the saturation surface measured? Can runs 1–4 be identified on Fig. 1? Any data on f as a function of t for each run would be interesting. Note that, if (6) and (7) were to hold, $z/(f - K)$ would be equal to $2t/(\theta_s - \theta_i)$.

(3) z as computed from (6) is equally sensitive to all three of K, d, and $(\theta_s - \theta_i)$. In view of the uncertainties in K and $(\theta_s - \theta_i)$, it would seem that the only point at which Hall's published data might test his analysis is on the proportionality of z to $t^{1/2}$. The discusser has examined the effect of water depth on infiltration by the 'diffusion' approach; the work is reported in detail in papers at present in press elsewhere. The solution includes the result that at small t, z varies as $t^{1/2}$, but that the exponent increases with time. This clearly fits Hall's data better than his analysis does. By the way, the discusser finds that the three experimental lines on Figure 1 give exponents 0.70, 0.69, 0.61. The mean of 0.67 is appreciably greater than the 0.6 mentioned by Hall.

Discussion of "A Correlation of the Characteristics of Great Storms"

by M. C. Boyer

[*Trans.*, **38**, 233–238, 1957]

Ven Te Chow (University of Illinois, Urbana, Ill., received June 13, 1957)—The writer is interested in the mathematics of storm characteristics as presented in this valuable paper, because he [*Chow*, 1953, 1954] has derived an equation for the average precipitation of practically identical form on the basis of similar assumptions. The writer has assumed that any observed storm pile can be converted into one which has circular horizontal sections, symmetrical with respect to the vertical axis of the pile and defined the storm pile as a three-dimensional representation of the rainfall isohyetals. By a mathematical treatment, a theoretical general equation for the average rainfall depth for all types of storms was developed. This equation is in the form of an infinite series

$$\bar{P} = a + bA^{0.5} + cA + dA^{1.5} + eA^2 + \cdots \tag{5}$$

in which $\bar{P}$ is the average depth of rainfall over an area A, and a, b, c, d, and e are coefficients.

The exponential term in (4) may be expanded into an infinite series as follows

$$\begin{aligned}\exp[-1.09(A/A_{0.5})^{0.5}] &= 1 - 1.09(A/A_{0.5})^{0.5} \\ &\quad + 0.594(A/A_{0.5}) - 0.216(A/A_{0.5})^{1.5} \\ &\quad + 0.059(A/A_{0.5})^2 - 0.013(A/A_{0.5})^{2.5} + \cdots\end{aligned} \tag{6}$$

Substituting (6) in (4) and simplifying

$$\bar{P} = 0.999P_{10} - 0.724P_{10}(1/A_{0.5})^{0.5}A^{0.5} + 0.297P_{10}(1/A_{0.5})A - 0.086P_{10}(1/A_{0.5})^{1.5}A^{1.5} + \cdots \quad (7)$$

This equation is practically identical in form with (5). Thus, $a = 0.999P_{10}$, $b = -0.724P_{10}(1/A_{0.5})^{0.5}$, etc.

D. A. Kraijenhoff van de Leur (Landbouwhogeschool Wageningen, Netherlands, received August 6, 1957)—Before developing his basic relation between precipitation rate and area, Boyer refers to the Hydrometeorological Report 5 (U. S. Weather Bureau and Corps of Engineers, 1947). In the latter a proportionality is suggested between the precipitation rate along an isohyetal and the logarithm of the area enclosed by this isohyetal. Boyer inverts this relationship by introducing a proportionality between the logarithm of the precipitation rate and the area enclosed by the isohyetal concerned. Therefore Boyer's approach and the method developed in the Hydrometeorological Report 5 are based on different assumptions. It was felt that further verification of Boyer's basic assumption would be desirable.

Haeuser [1919] studied a great number of concentrated heavy summer storms in southern Germany. The observations of approximately 5000 stations covering an area of 76,000 sq km (30,000 sq mi) were used for drawing isohyetals for storms of high intensity which occurred in the years 1908–1915. The resulting rainfall patterns were used for checking Boyer's basic assumption by plotting log P against $R = (A/\pi)^{0.5}$, P being the precipitation rate on an isohyetal, A the area enclosed by this isohyetal and R standing for its mean distance from the storm center.

In each of the 28 cases studied it was found that the plotted points showed a systematic divergence from a straight line. An example is shown in the top of Figure 4. This divergence suggests that the rainhill's shape cannot be closely approximated by a simple relation between the precipitation at a certain spot and its distance from the storm center. Both Boyer's study and the Hydrometeorological Report 5 present such a simple relation.

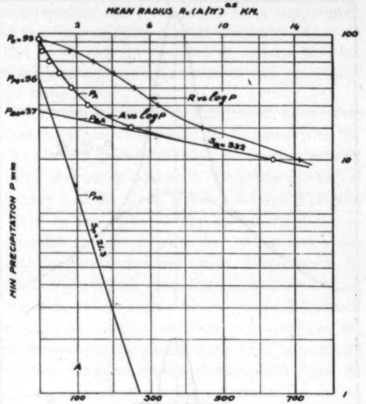

FIG. 4 – Graphical analysis of cloudburst near Jnzell, Germany, May 21, 1910, duration 1h 40m

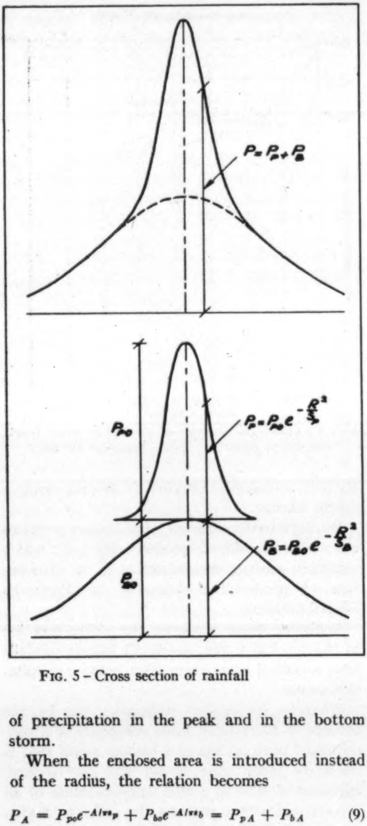
During a recent study on intense summer storms the writer developed another approach, which results in a better approximation of the distribution of precipitation indicated by Haeuser's rainfall-patterns.

Analysing these patterns, the writer was led to the conclusion that nearly all intense rainfalls have a central core where extra heavy precipitation occurs.

Whatever its physical explanation may be, the concept of the rainhill being composed of a concentrated peak on top of a bottom storm that is relatively more wide spread and flat topped, appeared to lead to a close approximation of all investigated storm patterns. In order to find a mathematical formulation of this concept, it was assumed that the vertical cross section over the storm center can be approximated by two Gaussian curves superimposed on each other and centered on the same axis, as shown in Figure 5. Thus the precipitation P along an isohyetal with a mean radius R can be expressed by

$$P = P_{po}e^{-R^2/s_p} + P_{bo}e^{-R^2/s_b} \quad (8)$$

P_{po} and P_{bo} stand for the maximum totals of precipitation in the storm center, resulting from respectively the peak and the bottom storm, s_p and s_b are coefficients determining the spreading



$P=P_p+P_B$
$P_p=P_{po}e^{-\frac{R^2}{S_p}}$
P_{po}
$P_B=P_{Bo}e^{-\frac{R^2}{S_B}}$
P_{Bo}

FIG. 5 – Cross section of rainfall

of precipitation in the peak and in the bottom storm.

When the enclosed area is introduced instead of the radius, the relation becomes

$$P_A = P_{po}e^{-A/\pi s_p} + P_{bo}e^{-A/\pi s_b} = P_{pA} + P_{bA} \qquad (9)$$

The precipitation along an isohyetal is plotted on a logarithmic scale against the enclosed area in rectangular coordinates and a curve is drawn through the plotted points. Then the diagram is split up into its components, the peak and the bottom storm, by drawing two straight lines in such a way that for any area the added ordinates P_{pA} and P_{bA} constitute a point on the curve of the relationship of A to log P. The intersections of these lines with the vertical axis mark the top values P_{po} and P_{bo} of respectively the peak and the bottom storm. The coefficients s_p and s_b can be derived from the declination of the straight lines.

By rotating and integrating the Gaussian distributions the following relation is found, giving the quantity of rain Q falling on an area A, enclosed by an isohyetal

$$Q = \pi s_p P_{po}(1 - e^{-A/\pi s_p}) + \pi s_b P_{bo}(1 - e^{-A/\pi s_b}) \qquad (10)$$

or

$$Q = \pi s_p(P_{po} - P_{pA}) + \pi s_b(P_{bo} - P_{bA})$$

The parameters s_p and s_b are known from the analysis and for any area A the values $(P_{po} - P_{pA})$ and $(P_{bo} - P_{bA})$ can be derived from the diagram. Q can be computed and consequently $\bar{P} = Q/A$.

It should be noted that $\bar{P} = Q/A$ introduced in (10) shows some resemblance with the result of Boyer's computations. The difference can be reduced to the following points: (a) The assumption of the Gaussian curve cross section which implies a proportionality between log P and the enclosed area A, instead of log P and the distance from the storm center as presented by Boyer. (b) The composite character of the rainhill against Boyer's simplified conception. Figure 6 shows the computed mean depth-area-curve. The general trend of this curve agrees with such curves as found by *Lott* [1953, 1954] both for a great storm of relatively long duration near Hallett, Oklahoma, and for a very intense small-area rainstorm near Holt, Missouri.

Recapitulating the comparison between Boyer's method and the one presented in this discussion: The latter produces a closer approximation of the distribution of rainfall when applied to the intense local storms, studied by Haeuser. As data on great storms are not available, the comparison between these two methods could not be extended to such distributions of rainfall as occur in extensive storms of long duration.

In hydrologic studies of small drainage basins

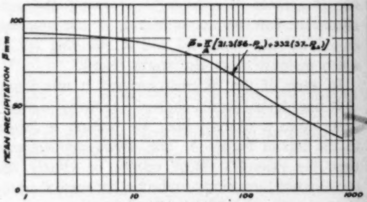


FIG. 6 – Mean depth-area-curve

and reclaimed areas thunderstorms are usually of major importance and in those cases the precipitation from a local peak may have a considerable effect on the resulting runoff. This effect will in many cases be amplified when the precipitation rate in the storm center is relatively high thus contributing even more strongly to the resulting direct runoff.

The solving of drainage problems in agricultural regions of the Netherlands therefore necessitates a thorough study of the characteristics of rainstorms, especially when a high watertable decreases the storage capacity of the soil. Consequently studies like Boyer's aiming at a numerical classification of rainstorms and using the considerable amount of precipitation data available in the United States, arouse great interest in this country.

M. C. Boyer (Indiana Flood Control and Water Resources Commission, Author's closure)—It is interesting and gratifying to learn that studies of the characteristics of great storms by Chow led him to develop an equation of relation between average precipitation and area which is practically the same as (4).

Attention is drawn by Kraijenhoff to the fact that the author's results are not in accord with the formula for the distribution of average rainfall with area as presented in Hydrometeorological Report 5 of the U. S. Weather Bureau. This was noted by the author during his studies and considerable thought given to it. The conclusion was that the intense summer storm, convective in its origin and covering a small area, does not behave the same as the large cyclonic storm. Krajenhoff reached the same conclusion and considers the pattern of the convective storm to be represented by two Gaussian curves superimposed. Such an interesting pattern is unique, so far as the author is aware.

Excellent data on rainfall over small areas in Illinois have been collected by the *Illinois State Water Survey* [1957] which will be of considerable interest to engineers concerned with this problem.

Discussion of "The Transport of Sand by Wind"

BY EDWIN F. FORD

[*Trans.*, **38**, 171-174, 1957]

R. A. Bagnold (Mark Beech, Edenbridge, Kent, England)—The simple Stokes law assumption appears to limit the applicability of the author's treatment to such fine dust particles as would in any case fail to describe the saltating trajectories indicated by Fig. 3. The reason for this failure is outlined in Jeffreys' paper under reference.

The fluid force on spheres of radius 0.0326 cm in the example given departs very appreciably from Stokes law. Taking the actual terminal fall velocity of such spheres as roughly typical of the wide range of resultant relative velocities obtaining during the whole trajectory, this is about 100 cm/sec (and not much different from that of real nonspherical grains of wide-blown sand). The fluid force on a sphere falling at this speed equals its own immersed weight, 0.33 dynes approx. The author's Stokes law expression (2) gives for the 100 cm/sec relative velocity a force of only 0.013 dynes. There is thus a 25-fold discrepancy due to the creation of turbulent eddies in the wake.

The Stokes law approximation might of course be justified on the assumption that the author's essential spin had the effect of inhibiting eddy formation. But this has not been established.

If approximate and workable equations of motion could be found for a single sand grain appropriate to conditions over the very awkward range of Reynolds number relevant, assuming some initial grain-free fluid velocity distribution, such equations may well be inapplicable to the simultaneous motion of many grains. For (a) the very appreciable influence of the moving grains on the fluid flow cannot be neglected [Bagnold, *Proc. R. Soc., A.*, **157**, 594, 1936], and (b) a typical grain path must include the effects of inevitable collisions between moving grains [Bagnold, *Phil. Trans., A.*, **249**, 235, 1956].

The problem is therefore more involved than the author's treatment would suggest.

Edwin F. Ford (3071 S. Woodrow St., Arlington, Va., Author's closure)—In the paper a number of simplifications of the problem were introduced. Of these perhaps the least tenable is the use of Stokes' law. It would possibly have been more appropriate to assume the drag to vary as the square of the relative velocity. As pointed out by Bagnold, an exact expression would have to take account of variations in the drag coefficient over a wide range of Reynolds numbers. This would considerably complicate the mathematics.

In the derivation given, a constant k is used in the expression for the lift, and so chosen as to give heights of trajectories about the same as those observed. A similarly adjusted empirical constant could have been included in the expression for the drag coefficient.

The sand-transport problem is certainly complex; this paper shows, however, that fairly simple equations can be set up which predict sand-grain behavior reasonably close to that actually observed.

Discussion of "Rainfall-Runoff Relations for Small Basins"

BY J. F. MILLER AND J. L. H. PAULHUS

[Trans., **38**, 216–218]

Louis A. Koffman (Corps of Engineers, Washington, D. C.)—The development of useful rainfall-runoff relations for small basins is an extremely useful extension of this valuable hydrologic tool. The authors are to be congratulated upon an excellent paper on an interesting subject presented in a clear and concise manner.

The writer is particularly interested in the subject because of his own efforts to develop some methods of computing approximate rainfall-runoff relations in various areas of the world, given a minimum amount of climatological facts and runoff data. In the course of the writer's investigations, he came to several conclusions which seem to be at variance, to some degree, with the authors'. Firstly, the authors state that experience has shown that the seasonal factor in the rainfall-runoff relation shows little change within a physiographically homogeneous region. The writer believes that authors may have meant to include similar climate as well as similar physiography. By definition, seasonal curves properly established should largely reflect the influence of the annual climatic cycle on runoff. In many areas of similar physiography, considerable differences have been known to exist in the evapotranspiration losses reflecting the effect of climatic differences. In place of accepting the seasonal curve from an area of one climate and using it for an area of another climate, the writer has obtained some workable runoff relations by adjusting the seasonal curves for variations in seasonal factors. The factors used included the mean air temperature in January and July, plus the length of the growing season and other climatic data. It seems to the writer, that if acceptable results were obtained by the authors in Georgia, using the seasonal curves of a rainfall-runoff relation developed in Maryland, the effect of differences in climate may have been only partially compensated in the hourly rainfall-hourly runoff portion of the runoff relation. If this were the case, the procedure illustrated in the paper will have limited application.

A further point which may need clarification is the adjustment made to compensate for change in the character of the drainage area at Little Falls during the period of record. The period of record at Bethesda, Maryland, used to develop the authors' rainfall-runoff relation, covers the period from 1946. As many people in the Washington area can attest, the watershed has experienced a phenomenal population growth. It is at present almost totally covered by a thickly-populated suburb of Washington, D. C., mostly built during the period of record. Such development must have affected the runoff relation in many ways. Certainly it must have destroyed the similarity between the Monocacy River basin, an area of low wooded mountains and rolling farm land, and the thickly-settled town of Bethesda which at present covers the watershed of Little Falls. In contrast to Bethesda, the Monocacy River basin has changed little during the last ten years. The increase of storm and domestic sewage at Little Falls plus the great increase of runoff from paved streets and roof tops are some of the most obvious changes which would affect the record of Bethesda.

The writer realizes that there are not many small drainage basins where the necessary data are available to enable the construction of a workable rainfall-runoff relation and that in any effort of this nature, compromise is necessary. However, he feels that a discussion of some of the necessary adjustments would add to the value of this useful paper.

J. F. Miller and J. L. H. Paulhus (U. S. Weather Bureau, Washington 25, D. C.; Authors' closure—The points raised by Koffman in his discussion show that he is well acquainted with the factors involved in the development of rainfall-runoff relations. The authors find no general disagreement between his views and theirs. Most of the apparent differences probably result from lack of adequate detail in the article.

In discussing the change with climate of the seasonal factor in the rainfall-runoff relation, Koffman is correct in presuming that the authors meant that there was little change within a climatologically and physiographically homogeneous region. This was not an omission but was due to the fact that the authors were referring to physiography in its broadest sense, which includes climate. Of course, there is no entirely satisfactory procedure for determining the climatic tolerances that can be permitted within a so-called climatologically homogeneous region. Admittedly, there is a general increase of precipitation from north to south in the region from New Jersey to Georgia, but there is also an increase of evapotranspiration. How much these variations would affect a rainfall-runoff relation for small basins is difficult to estimate.

In striving for brevity the authors made one omission that may have prompted some of the points raised by Koffman. They should have stated that the rainfall-runoff relations derived were for a special purpose. This purpose was to synthesize a record of annual flood peaks for a frequency analysis. Consequently, the rainfall-runoff relations needed to be satisfactory only for heavy, short-duration rainfalls that would normally produce the annual floods (the maximum peak discharge for each year) for basins no larger than a few square miles. This may explain in part why the man-made changes in the Little Falls basin during the period subsequent to 1946 may not have affected the results as much as one might expect. The difference between surface runoff from pervious and impervious surfaces is relatively less for intense rainfalls than for light or moderate rains. A time-trend study independently conducted for Rock Creek, also draining a suburban area of Washington, D. C., which has been highly developed during recent years, showed no appreciable changes in runoff characteristics.

The special purpose of the rainfall-runoff relations developed may also explain why satisfactory results were obtained without modification of the Monocacy River seasonal curves in the Little Falls relation. As Koffman states, reasonable differences would be compensated by a displacement of the rainfall curves, so that the runoff computations would be little affected. The limited application referred to by Koffman apparently includes the satisfactory estimation of runoff from intense local storms in the region from New Jersey to Georgia.

Discussion of "A Hypothesis of Formation of Mountains and Continents"

BY B. D. AGGARWALA AND EDWARD SAIBEL

[*Trans.*, **38**, 245–247, 1957]

Robert R. Wheeler (Meadows Building, Dallas, Texas; received May 16, 1957)—The authors have attempted to demonstrate mathematically that the cooling Earth suffered elastic failure primarily by "buckling rather than cracking" and that the resultant depressions localized the oceans while the humps formed the continents and mountains.

This conclusion ignores the few certain facts we know about the Earth's crust. It is readily observed that the continental crust has been repeatedly deformed by shortening accomplished by folding, faulting and loss of volume due to metamorphism. The oceanic crust shows no such tectonic pattern. It is profoundly different from the continental crust in strength, petrography, thickness, and elevation (reflecting its greater density).

In short, the continents could be described as light, granitic plates which terminate at the ocean borders and "float" within the same dense matrix that floors the oceans. The real problem is to determine how these light, continental plates were differentiated.

William A. Wiebenga (Bureau of Mineral Resources, Melbourne, Aust., received August 19, 1957)—The buckling suggested by the authors does not explain the basic difference in composition between the basaltic oceanic crust and the granitic or the metamorphic continental crust. Before buckling took place, the continents probably already existed.

Though the continental crust is usually considered as weaker than the oceanic part of the crust (implying that with mounting compressional stress it will break before the oceanic crust will), it is not certain whether it will buckle before the oceanic part of the crust will.

However, the geological evidence about geosynclines and mountain chains formed from geosynclines shows that the continental crust will buckle and break, often on the margin or boundary of continent with ocean, but that the main buckling movement is and must be downwards, and not upwards as the authors suggest. The mountain chains are formed at a later stage by compression of the sediments and vertical upwards movement to re-establish isostatic equilibrium.

The mechanism the authors describe mathematically may well be applied in a narrower sense to explain the formation of geosynclines. In that instance several checks on the mechanism may be suggested. For instance, after buckling the crust will crack by tensional stress on places where maximum bending moments occur. The cracks, accompanied by shears and faults, form excellent channels for subcrustal basic magma to rise to surface and near-surface level. This also explains the common association of basic dykes, basalts and dolerites with geosynclincal zones.

B. D. Aggarwala and *Edward A. Saibel* (Department of Mechanics, Rensselaer Polytechnic Institute, Troy, New York; authors' closure)—We are grateful to the discussors for their interesting remarks, and we are aware that the factors they bring up have not been taken into consideration. It was our intention to treat the problem quantitatively and in order to do this it was necessary, at the present time, to make very simplifying assumptions among which was that of homogeneity. The main purpose of the paper was to show the possibility of buckling as a mechanism for mountain formation. Having seen this possibility, it would now be of interest to consider a more realistic model.

Reviews, Abstracts, and Bibliography

CLAYS AND CLAY MINERALS, PROCEEDINGS OF THE SECOND NATIONAL CONFERENCE ON CLAYS AND CLAY MINERALS, Edited by Ada Swineford and Norman Plummer, Nat. Acad. Sciences—Nat. Res. Council Pub. 327, 503 pp., 1954, $4.00.

This volume contains the 36 papers presented at the Second National Conference on Clays and Clay Minerals which was held at the University of Missouri, Columbia, Missouri, October 15–17, 1953. The topics embrace much of the field of clay research. There are six papers on genesis and sedimentary petrology, eleven on description and properties of clays, five on techniques, four on soils, and ten on physico-chemical studies of clays.

The approach to the study of clays in this book is largely geological, but geophysicists, particularly hydrologists and oceanographers, will find many of the papers of interest to them.

CLAYS AND CLAY MINERALS, PROCEEDINGS OF THE THIRD NATIONAL CONFERENCE ON CLAYS AND CLAY MINERALS, Edited by W. O. Milligan, Nat. Acad. Sciences—Nat. Res. Council, Pub. 395, 579 pp., 1955, $7.00.

The success of the National Conferences on Clays and Clay Minerals which are held annually is demonstrated by this volume which contains 43 original contributions. It differs from its predecessors chiefly in the shift of emphasis to physico-chemical studies of clay systems. There are 18 papers on physico-chemical studies of clays. The importance of electron microscopy in the study of clays is well illustrated in this volume. There are more than 50 full pages of electron micrographs, many of which are superb illustrations.

Both Volumes 2 and 3 are records of progress in clay research and represent the divergent types of study being made in this country. The papers reflect the changing emphasis in the study of clays and clay minerals. The National Research Council is to be congratulated for the fine workmanship which has gone into the publication of these volumes.

GEORGE T. FAUST

The Geological and Geographical Institute of The Academy of Sciences of the Lithuanian S.S.R., *Transactions of the Regional Conference on the Study of the Quaternary Deposits of the Baltic States and the Byelorussian S.S.R.* (in Russian), Scientific Reports; v. 4, edited by V. K. Gudelis with the collaboration of A. B. Basalykas, K. K. Bieliukas, M. M. Capenko, V. A. Cepulyte, E. F. Grinberg, A. I. Jaunputnin, and K. K. Orviku; 444 pp., maps, diagrams, cross sections, tables; State Publisher of Political and Scientific Literature, Lithuanian S.S.R., Vilnius, 1957; ca. $7.00.

This volume consists of 27 papers that were presented at conferences held in Vilnius and Kaunas, Lithuania, in November 1955. Geographically, ten of these deal with Quaternary phenomena in Lithuania, six in Estonia, five in Byelorussia, four in Latvia, and three deal with the Baltic area in general.

Subjectwise, there are ten papers on the stratigraphy of Quaternary deposits in these areas, six on geomorphologic features, two each on the structure of the deposits, paleogeography, fresh water calcareous deposits, extent and retreat of the ice, and erratics, and one each on pollen studies, geologic evolution during the Quaternary, distribution of ground water, and karst phenomena.

The volume is well illustrated with diagrams, maps, and cross sections, but the few half tones did not reproduce well enough to be effective illustrations.

The 27 papers, comprising the first 370 pages of the book, are not integrated by an index, but in the 49 succeeding pages four of the authors and 12 other participants of the conferences discuss some of the general as well as specific aspects of the papers.

Notes and Personalia

Notes

Corrigendum—In the paper by R. O. Reid and K. Kajiura appearing in the October 1957 issue of the *Transactions,* pages 662–666, entitled "On the Damping of Gravity Waves Over a Permeable Sea Bed" the following corrections and changes should be made. On page 663, Eq. (2), change $-gh$ to $-gy$. In Eq. (3b), (13b), and (17), on the same page, replace p_2 by $p_2 + \rho g y$. These changes do not affect the rest of the development. Acknowledgment is made to Robert S. Arthur for detecting and reporting these changes.

Lowering of Permitted Level of Radiation Exposure—The Atomic Energy Commission has reduced by two-thirds the level of radiation exposure permitted for workers in atomic facilities in the Commission, people living near those facilities, and workers on atomic facilities of the contractors of the Commission. The new levels follow the recommendations made in January, 1957, by the National Committee on Radiation Protection and Measurement, which Committee noted that "changes in the accumulated maximum permissible dose are not the result of evidence of damage due to the use of earlier permissible dose levels, but rather are based on the desire to bring the maximum permissible dose into accord with the trends of scientific opinion." Under the new exposures, a worker may receive an average exposure of 5 rem (roentgen equivalent man), with a maximum in any one year not to exceed 15 rem.

Data Concerning the Underground Nuclear Explosion, September 19, 1957—The Atomic Energy Commission has announced the resultant yield of a deep underground nuclear test conducted in Nevada, September 19, 1957 as 1.7 kilotons. The shot was detonated at 16 hours 59 minutes 59.45 seconds GCT at the end of a tunnel 2000 ft long dug horizontally into the side of a mesa at the northern edge of the Yucca Basin in a layer of volcanic tuff. The coordinates of the detonation were 37° 11′ 44.8″ north, 116° 12′ 11.3″ west, elevation 6615 ft above mean sea level. The vertical distance from the detonation point to the mesa surface was 899 ft, and the slant distance to the side of the mesa was approximately 800 ft. Post-shot investigation of the tunnel and surrounding area confirm that the explosion was contained and that no radioactive materials escaped into the surrounding air. A detailed study of the area and the local effects of the detonation is in progress.

Meetings of the World Meteorological Organization—Regional Association III (South America) held its second meeting in Caracas, December 4–21, 1957. The group for the study on radiations of Regional Association I (Africa) met in Leopoldville, January 20–30. The Commission for Synoptic Meteorology held its meeting in New Delhi, January 21–February 14. The group for the study of sea ice of the Commission for Maritime Meteorology held its meeting in Washington, D. C., in February, 1958. The Joint ICAO-WMO Meeting on Telecommunications in Meteorology met in Geneva, February 24. Regional Association IV (North and Central America) will meet in Havana, March 18–28. Regional Association V (Southwest Pacific) will meet in Manila in April.

URSI Meeting—The U. S. National Committee for URSI combined with the Institute of Radio Engineers will hold their spring meeting at the Willard Hotel in Washington, D. C., April 24–26, 1958. Inquiries should be addressed to the U. S. National Committee for URSI, c/o National Research Council, 2101 Constitution Avenue, N.W., Washington 25, D. C.

RAIN-DISPERSING IN NORWAY—Experiments are under way on the west coast of Norway in an effort to reduce the rainfall in these regions. Initial results have been encouraging. Seeding with silver iodide has been successful in preventing humidity from condensing into raindrops long enough for the wind to blow the moisture elsewhere. There is the hope that this may be effective in dispersing the clouds in the lowlands and that they will finally gather and shed their rain over the higher mountainous regions inland, increasing the water supply for hydroelectric stations and giving aid in other regards in the economy of the country.

FELLOWSHIPS AND RESEARCH ASSISTANTSHIPS AT TEXAS A. AND M.—The Department of Oceanography of the A. and M. College of Texas has available fellowships and research assistantships to qualified holders of baccalaureate degrees for the academic year 1958–1959. There are three fellowships with stipends ranging from $1800 to $3000 and research assistantships ranging from $1800 to $2775. Matriculation and other fees, board, room rent, and laundry approximate $600 for the academic year and additional fees for out-of-state students of $150 a semester. Application forms may be secured from the Department of Oceanography and Meteorology, A. and M. College of Texas, College Station, Texas.

RESEARCH CENTER OF THE OHIO OIL COMPANY—The Ohio Oil Company now has work under way to complete the initial building program of its Research Center at Littleton, Colorado. Two new wings are being constructed, resulting in a 60 per cent increase in area to a total of about 70,000 square feet. The Laboratory is under the direction of W. Jack Yost.

DEDICATION OF THE COASTAL ENGINEERING LABORATORY AT GAINESVILLE, FLORIDA—This dedication was held December 3, 1957, in connection with the Coastal Engineering Congress that drew some 200 participants from thirteen countries. Per Bruun is the Director of the Laboratory.

PLANS FOR NATIONAL HURRICANE RESEARCH PROJECT—The U. S. Department of Defense has agreed to continue support of the U. S. National Hurricane Research Project through the hurricane season of 1958. One USAF B-47 Stratojet and two USAF TB-50 Superforts will be available.

NEW FINDINGS IN THE GULF OF ALASKA—The Coast and Geodetic Survey has announced the discovery of a deep, long trough in the bottom of the Gulf of Alaska which may be involved in tidal waves originating in that region. The chasm is 500 to 700 feet below the ocean floor and about two to three miles wide, stretching in a southwesterly direction across much of the Gulf below southern Alaska and is known to be at least 250 miles long.

NATIONAL SCIENCE FOUNDATION GRANTS—The National Science Foundation has recently announced 316 new grants totaling nearly $5,500,000 awarded during the quarter ending September 30, 1957. This brings the total grants since 1951 to 4,179, and the amount granted almost $66,000,000.

CONTINUANCE OF TEACHER TRAINING PROGRAM—The National Science Foundation is continuing its program in teacher training and will hold 108 institutes this coming summer at a cost of over $5,000,000. The Atomic Energy Commission is jointly sponsoring twelve of the institutes where courses in radiation biology for high school teachers are offered. It is expected that 5000 high school teachers and 250 college teachers will take the courses. Most institutes will pay a weekly stipend of $75, with additional allowances for travel and dependents. The program was started in 1953 with two institutes; in 1957 there were 96 institutes. A list of the institutions and which courses will be given may be secured from the National Science Foundation, but application for admission to the institutions must be made to the individual institution.

GRANT FOR SUPPORT OF HIGH-ENERGY PHYSICS—The National Science Foundation has made a grant of $160,000 to the Midwestern Universities Research Association (MURA) of Madison, Wisconsin, for basic research on high-energy accelerators with energies involving billions of electron volts. This grant is the seventh made to MURA for support of studies in this field. The new grant supplements funds received from the Atomic Energy Commission.

The Midwestern Universities Research Association is a group of 15 Midwest Universities which formed this Association in 1953 for research in high-energy physics and includes the following universities: Chicago, Illinois, Indiana, Iowa State College, State University of Iowa, Kansas, Michigan State, Michigan, Minnesota, Northwestern, Notre Dame, Ohio State, Purdue, Washington University (St. Louis), and Wisconsin. H. R. Crane of the University of Michigan is its president.

INTER-REGIONAL TRAINING SEMINAR ON HYDROLOGIC FORECASTING AND WATER BALANCE—This seminar was held at Belgrade, Yugoslavia, October 28 to November 16, 1957, and was sponsored by the World Meteorological Organization and the Hydrometeorological Institute of Yugoslavia. There were 28 participants from 19 countries. G. A. Alekseev of the Hydrometeorological Institute of the USSR presented a series of lectures on use of statistical methods in hydrology and G. P. Kalinin of the same organization discussed methods of flood routing. J. R. Mather of the Laboratory of Climatology of the Drexel Institute presented material on the water balance and Ray K. Linsley of Stanford University discussed techniques of flood forecasting used in the United States. C. W. Thornthwaite of the Laboratory of Climatology at Drexel was present for the first week and discussed the problems of water balance. Following the seminar, a five-day study tour of northern Yugoslavia was held, this permitting participants and lecturers to study stream gaging and sediment sampling in Yugoslavia.

NEW SWEDISH GEOPHYSICAL OBSERVATORY—The new Kiruna Geophysical Observatory of the Royal Swedish Academy of Science was formally opened July 2, 1957, upon the completion of the main observatory building and the ionospheric laboratory. This represented a culmination of a decade of planning and development. The Observatory is located in northern Sweden at 67.8° N, 20.4° E (geomagnetic, 65.30° N, 115.5° E). This bears an interesting relationship to the Geophysical Institute at the University of Alaska, with which it will cooperate closely. The Geophysical Institute is 64.9° N, 147.8° W (geomagnetic, 64.5° N, 104.6° W). A grant from the National Science Foundation aided in the equipping of the Observatory. Bengt Hultqvist is the Director at Kiruna. Attending the dedication ceremonies from the United States were Lloyd V. Berkner and J. Wallace Joyce.

MEETING OF SCOR—The Special Committee on Oceanic Research (SCOR) set up within the framework of the International Council of Scientific Unions held a three-day meeting at Woods Hole Oceanographic Institution in late August 1957 to lay plans for the future. It was noted that the three problems most in need for long-range studies included productivity of the sea, the ocean as a disposal area for industrial pollution including radioactive wastes, and the role of the ocean in climatic changes. Tentative plans were laid for future work including an expansion of deep-sea observations (the techniques for which have been improved greatly in the last few years) involving theoretical studies and further development of techniques, and a multiple ship operation in the Indian Ocean where a few oceanographic vessels have undertaken work, none using modern techniques. When the difficulties of observation techniques at great depths are overcome and the problems of accurate navigation are solved, probably large quantities of artificially radioactive material could be released in the ocean for tracer studies of the circulation of water masses. SCOR includes Roger Revelle, Chairman; G. E. R. Deacon, Vice-Chairman; G. Böhnecke, Secretary; and the following members: Anton Bruun (Denmark), L. R. A. Capurro (Argentina), Y. Miyake (Japan), L. Zenkevitch (USSR), M. N. Hill (England), H. Mosby (Norway), E. Steemann Nielsen (Denmark), N. B. Marshall (England), Y. LeGrand (France), N. W. Rakestraw (USA), and C. O'D. Iselin (USA).

NEW COMMITTEE ON OCEANOGRAPHY ESTABLISHED—A new Committee on Oceanography to serve especially the needs of the Fish and Wildlife Service, the Department of Defense, and the Atomic Energy Commission has been established in the Earth Sciences Division of the National Academy of Sciences-National Research Council. Chairman of the new Committee is Harrison Brown. The other members are: Maurice Ewing, C. O'D. Iselin, Fritz Koczy, Sumner Pike, Roger Revelle, Gordon A. Riley, Milner B. Schaefer, and Athelstan Spilhaus, with Richard C. Vetter serving as Executive Secretary.

CRUISES OF THE SCRIPPS INSTITUTION OF OCEANOGRAPHY—The second of three IGY cruises of the Scripps Institution of Oceanography will depart from San Diego, March 27, 1958. The purpose of this cruise is to study ocean currents in the vicinity of the Equator, particularly their Equatorial Undercurrent. The Scripps vessel *Horizon* will be joined in the work at the Equator by the *Hugh M. Smith* of the Pacific Oceanic Fishery Investigations. They expect to return about June 9.

The third IGY Cruise will leave San Diego on August 1 and will involve three Scripps vessels, *Horizon*, *Baird*, and *Stranger*, and possibly will be joined by a frigate from Colombia. The purpose of this cruise is to study short-period fluctuations in the Equatorial Countercurrent, the center of which is near 8° N, 110° W. The return to San Diego is scheduled for September 30.

NEW GRADUATE COURSE IN HYDROLOGY AT CLARK UNIVERSITY—Clark University is giving a new graduate seminar in the geographic aspects of hydrology. The seminar is being conducted by David H. Miller of the Quartermaster Research and Engineering Center at Natick, Massachusetts.

NEW SPACE TECHNOLOGICAL LABORATORY—The Ramo-Wooldridge Corporation of Los Angeles has announced the establishment of a Space Technological Laboratory as an outgrowth and extension of its Guided Missile Research Division.

SURFACE MEASUREMENTS OF GRAVITY AT SEA—Lamont Geological Observatory has announced that recently surface measurements of gravity at sea were made using a new sea gravimeter developed by Anton Graf of Germany. The instrument was mounted on a platform stabilized by a gyroscope aboard the *U.S.S. Compass Island*. The work was under the direction of J. Lamar Worzel.

NEW ANTARCTIC PUBLICATION IN ARGENTINA—Volume 1, Number 1, of the ***Boletin del Institute Antartico Argentino*** was issued under date of May 1957 by the Antarctic Institute of Argentina of which Rodolfo N. Panzarini is the Director.

NEW EARTH SCIENCES DEPARTMENT AT STANFORD RESEARCH INSTITUTE—Recognizing the growing emphasis on research in various aspects of the Earth sciences, Stanford Research Institute has established a Department of Earth Sciences in its Physical Sciences Division under the Chairmanship of Richard M. Foose, formerly of Franklin and Marshall College. This Department will deal especially with the hard-rock and mineralogical aspects of the geophysical sciences.

NEW OPTICAL ASTRONOMICAL OBSERVATORY—The Association of Universities for Research in Astronomy (AURA), a newly organized group involving seven universities (California, Chicago, Harvard, Indiana, Michigan, Ohio State, and Wisconsin), all having large observatories with active programs in astronomical research, has completed arrangements with the National Science Foundation to build and operate a new observatory for basic research. R. R. McMath of the McMath-Hulbert Observatory in Michigan is the President. The main office will be in Phoenix, Arizona. The site is not yet chosen, but one of three Arizona sites is the likely choice. The initial plans call for telescopes of 80 and 36 inches.

NEW ZEALAND PROGRAM FOR RADIOCARBON DATING—The New Zealand Department of Scientific and Industrial Research, in its studies on industrial effects, has found that the effect is the same in the atmosphere of the Southern Hemisphere as in the Northern Hemisphere. The exchange time for atmospheric circulation between the two hemispheres is less than twelve years, and the mean life of a carbon dioxide molecule, before being absorbed into the ocean, is less than seven years. They have substantiated the idea that H-bomb tests tend to enrich the atmosphere in C_{14} and that the C_{14} specific activity of the atmosphere was increased by four per cent in the interval from February, 1955, to October, 1956. The study of C_{14} activity of sea water from Makara has continued, and already an increase has been detected. Further measurements are contemplated to demonstrate this increase, and sea-water samples from varying depths have been collected from a station over the New Caledonian Trench in the expectation that the results will give base-line data on the age of the ocean before the H-bomb effect and offer scientists opportunity to estimate the size of the upper and lower reservoirs of the ocean.

RADIO ENGINEERS' CONFERENCE—The Southwestern Institute of Radio Engineers will hold a conference and an electronics show in San Antonio, Texas, April 10-12, 1958.

Personalia

KEITH E. ANDERSON, formerly Regional Drainage and Groundwater Engineer for the Bureau of Reclamation in the Pacific Northwest, has opened an office in Boise, Idaho, as consultant in engineering and geology, with specialization in groundwater, drainage, and irrigation problems.

JAMES L. DYSON, Head of the Department of Geology at Lafayette College, has received an award of $500 from the Thomas R. Jones Fund for the Reward of Superior Teaching at Lafayette College. This is the second time in two years that he has received the award.

MILTON GREENBERG, Director of the Geophysics Research Directorate, Air Force Cambridge Research Center, has been awarded the Medal for Exceptional Civilian Service by the Secretary of the Air Force. He was cited for "his unusual efforts as an organizer, manager, and leader" which "aided greatly in the development of an organization that has earned an outstanding reputation for scientific and technoloigcal achievement and has made important contributions to the research and development program of the U. S. Air Force."

LEONARD C. HALPENNY has announced the establishment of the Water Development Corporation in Tucson, Arizona, specializing in problems of groundwater hydrology and related fields.

PAUL K. KURODA has left his work as Associate Professor of Chemistry at the University of Arkansas and has taken up new duties with the Argonne National Laboratory as Associate Chemist.

WALTER D. LAMBERT, Chief of the Gravity and Astronomy Section of the U. S. Coast and Geodetic Survey, retired, and now Consultant in Geodesy at Ohio State University, was awarded an honorary degree of Doctor of Science recently by Ohio State University.

GORDON A. MACDONALD has left his work with the U. S. Geological Survey in Denver to accept an appointment as Professor in the new Institute of Geophysics at the University of Hawaii and the Department of Geology at the University. He took up his new duties in February, 1958. In connection with this work with the Institute of Geophysics, he expects to establish volcano research in cooperation with the Hawaiian Volcano Observatory of the U. S. Geological Survey.

ALFRED C. REDFIELD of Woods Hole Oceanographic Institution is a national Sigma Xi lecturer. His topic is "The Proportions of Things in the Sea."

FREDERICK D. ROSSINI, Head of the Department of Chemistry of the Carnegie Institute of Technology and Chairman of the Division of Chemistry and Chemical Technology of the National Research Council, was one of the principal speakers at the Indian Science Congress which opened on January 6, 1958, in Madras.

PAUL A. SIPLE has returned from a year at the South Pole, during which time he was scientific head of the United States base established there. He was recently awarded the American Geographical Society's David Livingstone Centenary Medal. He has also been named the recipient of the Army's Distinguished Service Award for his scientific leadership at the South Pole.

ATHELSTAN SPILHAUS, Dean of the Institute of Technology at the University of Minnesota, has resigned his membership on the Board of UNESCO, effective as soon as the U. S. Government has selected a replacement.

LORENZ G. STRAUB, Head of the Civil Engineering Department of the University of Minnesota and Director of the St. Anthony Falls Hydraulic Laboratory, has been given one of the research prizes of the American Society of Civil Engineering.

HAROLD C. UREY, Professor, Enrico Fermi Institute for Nuclear Studies, University of Chicago, and Nobel Prize winner in Chemistry in 1934, has been appointed Professor of Chemistry at Large at the University of California. His laboratory and headquarters will be at the La Jolla campus beginning in June, 1958.

WARREN WEAVER, Vice President of the Rockefeller Foundation for Natural and Medical Sciences, has been given the Public Welfare award of the National Academy of Sciences.

HANS F. WINTERKORN, Professor of Civil Engineering at Princeton University and specialist in the field of soil stabilization, has been awarded the Officer's Cross of the Federal Order of Merit, the highest civilian decoration of the German government.

CHARLES FRANKLIN BROOKS, Professor Emeritus of Meteorology at Harvard University and until his retirement in August, 1957, Director of the Blue Hill Meteorological Observatory of Harvard University, died January 8, 1958, at the age of 66. He was born in St. Paul, Minnesota, and took his baccalaureate degree at Harvard in 1911 and his doctorate from the same university in 1914. He founded the American Meteorological Society in 1919 and served faithfully as Secretary of that organization from the time of its founding until 1954. He had been a member of the American Geophysical Union since 1929. One of his many contributions to science appears in this issue of the *Transactions*, in collaboration with Mrs. Brooks. His devotion to science and his fellow man was an inspiration to all who knew him.

HENRY C. CORTES, Vice President and Director of Magnolia Petroleum Company, died in Honolulu December 6, 1957, while enroute with Mrs. Cortes to spend Christmas with his daughter and her family on Formosa. He was born in Houston, Texas, and pursued studies at the University of the South, and was recently awarded an honorary doctorate. He had planned to retire from his duties with Magnolia at the end of

1957. He began his professional career with the Vacuum Oil Company, where he continued serving as Director of Geophysics from 1928 to 1932 at which time there was a merger with the Magnolia Petroleum Company. He continued his duties as Director of Geophysics for the combined companies until 1946, when he was made Assistant Manager of the Exploration Division. He became a member of the Board of Directors in 1954 and in 1956 was made a Vice President of the company. He received wide recognition for his work in offshore oil exploration which involved fundamental and applied research. He had been a member of AGU since 1944.

Reginald Aldworth Daly, Sturgis-Hooper Professor Emeritus in Geology at Harvard University, died September 19, 1957, at the age of 86. He was born at Napanee, Ontario, took his baccalaureate degree from the University of Toronto in 1891, his master's degree from Harvard in 1893, and his doctorate in 1896. He studied at the University of Heidelberg and the Sorbonne. He was the recipient of a number of honorary doctorates and a member of the National Academy of Sciences. He was a recognized international authority on various geological subjects, especially those relating to structural geology. He was one of the original members of AGU, and in 1946 was designated as the Eighth Recipient of the William Bowie Medal.

Roy Waldemar Goranson, member of the staff of the University of California Radiation Laboratory, died December 25, 1957, at the age of 57. He was born at New Westminster, British Columbia, Canada, took his baccalaureate degree from the University of British Columbia in 1922, his master's degree from Harvard in 1923, and his doctorate also from Harvard in 1931. He began his career as a fellow in Optical Mineralogy from 1924 to 1926, and from 1926 to 1948 with the exception of the war years was with the Geophysical Laboratory of the Carnegie Institution of Washington. From 1948 to 1952, he was at the Los Alamos Scientific Laboratory. He took up his duties at the Radiation Laboratory in 1953. He had been a member of AGU since 1930, and had served as a member of various committees.

Bjørn Helland-Hansen, long one of the world's outstanding leaders in oceanography and Past President of the International Union of Geodesy and Geophysics, died in Norway, September 7, 1957, in his 80th year.

Elbridge Churchill Jacobs, Professor of Geology and Mineralogy at the University of Vermont, retired, died December 12, 1957, at the age of 84. He took his bachelor's degree from Massachusetts Institute of Technology in 1896 and his Master of Science degree from Columbia. He began his career as assistant in mineralogy at Massachusetts Institute of Technology and in 1899 took up duties as instructor in chemistry and mineralogy at the University of Vermont, where he continued until his retirement in 1944. During this interval, however, he was active in related work on flood-control investigations and served as State Geologist for Vermont from 1943 to 1947. He had been a member of AGU since 1934.

John Christian Jensen, Professor of Physics of Nebraska Wesleyan University, retired, died on his birthday, October 19, 1957, at the age of 77. He was born at Utica, Nebraska, took his baccalaureate degree from Nebraska Wesleyan in 1909, his M.A. from Nebraska in 1916, and his Ph.D. from Nebraska in 1939, studying also at the University of Iowa in 1916 and the University of Chicago in 1921. He began his professional career in school-teaching work in 1903. In 1907, as a student, he began teaching at Nebraska Wesleyan where he continued until his retirement in 1952. He served in many other capacities at the University, such as Dean of Men and as Coordinator of the Civil Aeronautics Administration. After his retirement in 1952, he was Visiting Professor at Cornell College in 1952 and 1953 and had been doing consulting work in physics since 1953. He became a member of AGU in 1930 and a Life Member in 1952.

Robert Talbot Knapp, Professor of Hydraulic Engineering at California Institute of Technology, died November 7, 1957, at the age of 58. He was born in Loveland, Colorado, took his baccalaureate degree from Massachusetts Institute of Technology in 1920 and his Doctor's degree from California Institute of Technology in 1929. He began his professional career as a designer for the Gay Engineering Corporation in 1920, but in 1922 he took up duties as instructor at the California Institute of Technology and, excepting for various war assignments, continued his work there until the time of his death. He served as consultant in various engineering work and in 1929 was chosen as a Freeman traveling fellow in hydraulics, devoting a year to study in Europe. Incidental to his work at California Institute of Technology, he undertook various assignments with respect to the Department of Agriculture and the designing of equipment for the Bureau of Reclamation. During war years he was with the Office of Scientific Research and Development. He had been a member of AGU since 1934.

Frederick Law Olmsted, noted Landscape Architect, whose skill was reflected in the development of Central Park in New York, the Mall, Rock Creek Park, and other areas in Washington, and the parks of many other cities, died in Malibu, California, December 26, 1957, at the age of 87. He was born on Staten Island, New York, and took his baccalaureate degree from Harvard University in 1894, receiving an honorary master's degree from Tufts in 1926. He began his work as Landscape Architect in 1895 as a member of Olmsted Brothers of Brookline, Massachusetts, and developed his work through this company up to within a short time before his death. He became a member of the American Geophysical Union in 1949.

Howard Edwin Tatel, Research Physicist of the Department of Terrestrial Magnetism of the Carnegie Institution of Washington, died November 15, 1957, at the age of 43. He was born in New York, and took his baccalaureate degree from Massachusetts Institute of Technology in 1935, his master's degree in 1936, and his doctorate from Stanford under a Rosenberg Science Fellowship in 1940. He did research work in physics at the University of Michigan, worked with the Carnegie Institution of Washington from 1941 to 1943, and with the Applied Physics Laboratory of Johns Hopkins University from 1943 to 1947. In 1947, he returned to the Carnegie Institution where he continued until the time of his death. Only a short time before his death, he had returned from a scientific expedition in Bolivia and the Highlands of the Andes on work connected with the International Geophysical Year. He had been a member of AGU since 1950.

Union, Section, and Committee Activities

Minutes of Executive Committee Meeting, American Geophysical Union October 25, 1957

The meeting was called to order at 10h 07m in the Conference Room of Assistant Secretary of the Interior Aandahl, Room 6622 Interior Building, Washington, D. C., by Vice President Lloyd V. Berkner in the absence of President Ewing, who was unable to attend because of illness.

Present—P. H. Abelson, L. H. Adams, L. T. Aldrich, W. W. Atwood, Jr., Lloyd V. Berkner, Walter H. Bucher, J. J. Capello, S. D. Cornell, Earl G. Droessler, Robert E. Gebhardt, Harry H. Hess, Albert J Hoskinson, B. F. Howell, Jr., H. R. Joesting, J. W. Joyce, W. C. Krumbein, H. E. Landsberg, John Lyman, Thomas Maddock, Jr., A. G. McNish, L. M. Murphy, Jerome Namias, James H. Nelson, Charles Pierce, John C. Reed, Roger Revelle, A. N. Sayre, J. F. Schairer, Waldo E. Smith, and C. A. Whitten.

Approval of minutes—The minutes of the Executive Committee meetings of April 28 and May 1, 1957, published in the August 1957 issue of the *Transactions* (pp. 599–609), were approved.

General Secretary's Report

The last report of the General Secretary is recorded in the minutes of the Executive Committee meeting of April 28, 1957 published in the August 1957 issue of the *Transactions* (pp. 599–602).

The officers of the Union met on July 25, 1957, some of the purposes of which were to work out new arrangements for an advertising representative (Howland and Howland of New York are now undertaking this work), establish new advertising rates, and discuss the possibilities of joining our *Transactions* with the *Journal of Geophysical Research*, and issuing the *Transactions* on a monthly basis. At that time the officers, recognizing that additional revenue would be necessary to maintain the *Transactions* at the present level of excellence, considered various means of increasing revenue. One suggestion was to make a per-page charge of $10 which would entitle the author to 100 reprints. Small numbers of additional reprints would be priced at a level somewhat higher than is now charged, and large numbers would be furnished at a price about equal to the present charges. In view of the wide variation in practice in different disciplines and different journals, this matter should deserve wide and open discussion among members of the various Sections so that their representatives will be prepared to present the pros and cons of this and alternative schemes.

Also, the group went over with Chairman Joyce of the Committee on International Participation and Director Atwood of the Office of International Relations of NAS-NRC the proposed new Statutes and By-Laws for the IUGG and made positive recommendations.

Chairman Gerson of the Committee on AGU Relations with IGY was present, and there was a brief discussion of the work of that Committee which will be reported on in detail later at this meeting.

The monograph series was also discussed, and it was concluded that to finance this series properly we must secure a revolving fund from a foundation or some other source. However, before such financing can be gained, we must have in mind some rather firm titles for further symposia or groups of papers suitable for the monograph series.

The striking of additional Bowie medals by the U. S. Mint in Philadelphia was approved.

Publications—The following issues of the *Transactions* have been printed and distributed since our last meeting:

April 1957: 141 numbered pages of text plus 90 numbered pages of Directory plus 37 unnumbered pages including 17 pages of paid advertising; edition of 6300

June 1957: 160 numbered pages of text plus 16 unnumbered pages including 9½ pages of paid advertising; edition of 6300

August 1957: 194 numbered pages of text plus 26 unnumbered pages including 18½ pages of paid advertising; edition of 7200

The August issue was released in a larger edition in order that copies might be given to the delegates of the Eleventh General Assembly of the International Union of Geodesy and Geophysics without charge.

The Executive Committee last spring approved in principle the idea that we should indicate our willingness to publish in our *Transactions* the new *IGY Bulletin* to be issued by the U. S. National Committee for IGY if this could be done without decreasing the number of text pages and without cost to AGU. Arrangements have since been worked out along these lines, and *IGY Bulletins* 1 and 2 were published in the August issue of the *Transactions* and *Bulletins* 3 and 4 will appear in the October issue. In working out arrangements for this, the format was modified somewhat from ours and a somewhat larger type font was used to make for easier reading. This material does not receive the same scrutiny by the Editorial and Publication Committee as other material submitted for publication in the *Transactions*. Closer scrutiny is not possible (1) because of the very tight time schedule on which our printer does this job, and (2) the fact that it is essentially an IGY news letter which the IGY Committee feels should be published. There are deviations also from our format standards other than the type font and size which are not deemed to be objectionable. Many of our members feel that this material is a valuable addition to the *Transactions*. It also provides a desirable opportunity of cooperating with the IGY Committee.

The October 1957 issue of the *Transactions* is about ready for distribution and possibly will be packed for the mails on Saturday, October 26. The printer again has been somewhat slow in making delivery, but in this particular case it gave Howland and Howland of New York a little more time to secure additional advertising. The October issue will contain 188 numbered pages of text plus 20 unnumbered pages, including 11½ pages of paid advertising, with an edition of 6200. We are hopeful that the number of pages of advertising will now begin to increase substantially. Starting with the August issue, the basic charge per page of advertising was established at $250 instead of $100. We are attempting to emphasize in our advertising prestige and good-will, or public relations, rather than just straight commercial advertising. Those of you who are in influential positions in your companies, or have cordial relations with companies that you feel should appropriately advertise in the *Transactions*, can be helpful in arranging for advertising or indicating to the office of AGU companies that might consider the prestige and good-will of advertising in the *Transactions* worth while. This aid is most urgently needed.

The Editorial and Publication Committee has met regularly at bimonthly intervals to consider the many problems of the *Transactions*, including its continual improvement.

We have recently received notice from the printer that our printing costs are going up about 20 per cent (about $5000 a year) starting January 1, 1958. Consequently, if we are to maintain the present high standards, it appears that it will be necessary to augment our income from publications.

The officers have discussed and, I believe, other groups are also considering the desirability of attempting to issue our *Transactions* on a monthly basis, perhaps starting in 1959. Negotiations toward combining the *Transactions* with the *Journal of Geophysical Research*, if appropriate financial arrangements can be made, seems to be a desirable objective.

Negotiations have been completed with the Johnson Reprint Corporation for reprinting the out-of-stock numbers of our *Transactions* and for the sale of our stock of *Transactions* prior to 1954. The stock of *Transactions* prior to 1954 has been turned over to Walter J. Johnson, Inc., and payment therefor is expected in the near future.

Plans for continuing the Geophysical Monograph Series are still in abeyance. We must find ways and means for implementing this series so that appropriate documents may be printed. We are still seeking a fund of $50,000 to $100,000 to set up as working capital, and any suggestions to this end are invited.

We have received grants totaling $40,900 from the National Science Foundation to cover the Russian translation project for the year. This will involve the translation and publication of *Izvestiia* (Geophysics Series), the translation and publication of geophysical abstracts relating to material published in eastern Europe, Russia, and the mainland of China, and a review or survey of *Trudy* (of the Geophysical Institute) to see what particular material should be set up as special translation projects. So far, the Pergamon Press, with whom arrangements have been completed for the translation, publication, and sales work, has not produced any complete copies. It is expected that No. 2 of *Izvestiia* for 1957 will be forthcoming soon, with No. 1 to follow shortly thereafter. An Editorial Board, consisting of Perry Byerly (Chairman), Walter B. Langbein, John Lyman, F. W. Reichelderfer, A. E. Scheidegger, Waldo E. Smith, and Victor Vacquier, has been established to advise on this project. A questionnaire was mailed out to about a thousand addresses in early September with the main purpose of establishing a list of about 500 who would be able to help us in shaping this project in the months and years ahead.

Membership—Earl G. Droessler has taken over actively as Chairman of the Committee on Membership. He has established sections responsible for certain phases of the work. The following section chairmen have been designated: Elliott B. Roberts, Chairman for Government Memberships; B. F. Howell, Jr., Chairman for Academic and University Memberships; Nelson C. Steenland, Chairman for Industrial and Commercial Memberships (both individual and corporation); Paul A. Smith, Chairman for Admissions; and Willis B. Foster for Brochures and Publicity. So far, activity has been greatest among the government group. However plans for implementing other phases of the membership drive have shown much progress and should soon be in full swing. New brochures have been issued to facilitate the work.

Membership data are:

Membership as of April 25, 1957	4980	
Reactivated	1	
New members, April 25 to October 16, 1957, including 14 applications now being processed toward membership	229	5210
Resigned	32	
Inactive	3	
Dropped	136	
Deceased (reported since April 25, 1957)	18	189
		5021

Dues unpaid—As of October 16, 1957, the following dues were unpaid:

Owe for 1957	285
Owe for part of 1957	13
Owe for 1956 and 1957	172
Owe for part of 1956 and all of 1957	12

Deaths—The following 18 deaths have been reported to the Union office since our last meeting: Robert W. Kellogg, April 13, 1956; Paul L. Heslop, November 7, 1956; Paul S. Kraus, November 10, 1956; William H. Twenhofel, January 7, 1957; Hans Kramer, February 16, 1957; O. J. Backus, February 24, 1957; Juan Jagsich, April 3, 1957; John W. Pritchett, April 19, 1957; C. E. Deppermann, May 8, 1957; George W. Trauger, June 1, 1957; John C. Rabbitt, June 10, 1957; Herbert R. Morgan, June 11, 1957; Arthur A. Lane, June 17, 1957; Eugene F. Bangs, June 22, 1957; Irving Langmuir, August 16, 1957; C.-G. Rossby, August 19, 1957; H. U. Sverdrup, August 20, 1957; Ladislao Adler, September 4, 1957.

Finances—Below is a brief statement of our assets as of October 1, 1957, with comparisons for the last two years.

	Oct. 1, 1957	Oct. 1, 1956	Oct. 1, 1955
Cash balance	$17,728	$18,216	$14,152
Permanent Fund	14,055[a]	13,075[a]	12,348[a]
Emergency Fund	1,000	1,000	1,000
T. M. & E. Award Fund	1,288	1,268	985
Russian Translation Fund	40,067	......	......
	$74,138	$33,559	$28,485

[a] Does not include accumulated interest on $2368 of U. S. Savings Bonds.

After making adjustment for the payment for the August issue of the *Transactions*, we have about $4500 less than we had a year ago, and in that fiscal year we incurred a deficit of about $2000. The increase in the cost of printing between January 1 and July 1 will amount to about $2500. Therefore, we have cause for concern over our financial situation. We are hopeful that advertising and membership increases will improve this situation before the end of the current fiscal year, but, if not, prompt steps will need to be taken in 1958 to augment the Union's income.

The financial statement for the year ending June 30, 1957 has been completed and audited by the Audit Committee, and will be presented later in this meeting.

Office staff and jobs—At the present time there are four full-time staff members including a student from Antioch College who is with us as a part of her college work. The office staff includes James J. Capello, Ethel G. Sanders, Susan Davis (the student), and Waldo E. Smith, Executive Secretary. In addition, Glenda Quinn Olmstead, who has been a full-time member of our staff at various times in the past, is continuing with us about half time, Barry Modlin (a student at George Washington University) about a quarter time, and Marc Klaben (a high school student) after school in the afternoon.

Quarters—We continue to occupy five rooms in the building of the American Association for the Advancement of Science at 1515 Massachusetts Ave., N.W. These are proving very satisfactory for our present requirements.

International matters—The Eleventh General Assembly of the International Union of Geodesy and Geophysics was held in Toronto, September 3–14, 1957. About 1400 attended from some 50 countries, with about 500 in attendance from the United States. At that meeting the decision was made to hold the Twelfth General Assembly in Finland, July 25–August 8, 1960. J. Tuzo Wilson of Canada was elected President for the triennium now beginning, with V. V. Beloussov of USSR and W. A. Heiskanen of Finland as Vice Presidents. G. Laclavere was reelected General Secretary. Joseph Kaplan was elected President of the Association of Geomagnetism and Aeronomy and H. G. Wilm as President of the Association of Hydrology. C. A. Whitten was elected Vice President of the Association of Geodesy, Horace R. Byers as Vice President of the Association of Meteorology, and J. Frank Schairer as Vice President of the Association of Volcanology. Amendments were made to the Statutes and By-Laws. A report on the meeting will be given by President Ewing, who served as Chief Delegate, and more details will be presented by Chairman Joyce of the Committee on International Participation later at this meeting.

Meetings—The Pacific Northwest Regional Group will hold a meeting October 29–30, 1957, in Pullman, Washington, and the Executive Secretary will attend. It is felt that these activities should perhaps have greater support from the national organization, and upon the urging of members of the Regional Committees it was decided that one of the officers should attend each of these regional meetings.

The regional meeting of the Pacific Southwest Regional Group will be held in Pasadena, February 6–7, 1958. The General Secretary plans to arrange his schedule so as to attend that meeting.

Our annual meeting is set for May 5–7, 1958. We shall have a report from Chairman Abelson of the Committee on Meetings with regard to plans for this. Suggestions for symposia that have come into the office include one on aeronomy, perhaps along the lines of the one held in Toronto. Another has been suggested by the Special Committee on Cosmic-Terrestrial Relationships (E. H. Vestine, Chairman) and still another involving phases of geochemistry under the guidance of Abelson. We will leave in the hands of the Committee the development of appropriate plans.

It was anticipated that a meeting of AGU might be held in cooperation with the meeting of the American Association for the Advancement of Science between Christmas and New Year's Day in Indianapolis, and Edward M. Brooks of St. Louis was invited informally to explore this. AGU expects to cosponsor a symposium on "Weather and its relation to man" arranged by Section M (Engineering) of the AAAS. The American Meteorological Society will also be a cosponsor.

A Conference on Atmospheric Chemistry of the Compounds of Chlorine and Sulphur is to be held in Cincinnati, November 4–6, 1957, in cooperation with the U. S. Public Health Service. James P. Lodge, Jr., of that Service and Chairman of the Committee on Atmospheric Chemistry of our Section of Meteorology has been instrumental in arranging the meeting. The National Science Foundation has made a grant of $4000 to cover the cost of travel of foreign participants. No provision has been made as yet for the publication of the papers to be presented.

Statutes and By-Laws—The ballot has not yet been sent out concerning the changes in the Statutes and By-Laws approved by the Executive Committee at its meeting last spring because several meteorologists have objected to changing the name of the International Association to Geomagnetism and Aeronomy. The ballot was withheld until the close of the meeting in Toronto to see whether this decision might be reversed. Inasmuch as no action to reverse this decision was taken, it is planned that the ballot will be prepared and mailed soon. Also, some persons felt that the change in name of the Section of Terrestrial Magnetism and Electricity had not been formally approved by that Section of the AGU. At the meeting in 1956, nine voted to change the name to Geomagnetism and the Upper Atmosphere and six voted to change it to Geomagnetism and Aeronomy. The President of the Section, feeling that the vote was not decisive in view of the small number voting, recommended to the Executive Committee that the name be changed to Geomagnetism and Aeronomy to correspond to that of the International Association. This action has recently been challenged by a member active in the Section. However, since the Statutes and By-Laws of AGU do not require concurrence by the Section in the change, it is planned to proceed with this matter in the near future unless objection is raised in this meeting.

International Geophysical Year—In addition to the comments concerning the IGY activity noted above, a further report will be given by Chairman Gerson.

Education in Geophysics—A committee has now been appointed under the chairmanship of John E. Nafe and including H. R. Byers, C. T. Elvey, H. H. Hess, Patrick M. Hurley, Frank Press, Roger Revelle, Athelstan Spilhaus, C. W. Thornthwaite, James A. Van Allen, and H. G. Wilm. The committee perhaps has not yet had opportunity to organize, but later we will have a preliminary report from Nafe.

American Geological Institute—Henry R. Joesting completes his second term as one of our directors on the Board and cannot be reappointed. Appointment of two new directors is pending in the hands of President Ewing.

Miscellaneous—At the meeting in Toronto, where the Canadians made special arrangements for the entertainment of the wives of delegates, the question was raised by certain American women in attendance whether our annual meeting should provide for a Ladies' Committee to give special attention to entertainment of the ladies that may accompany their husbands to our meeting. The policy of AGU in the past with regard to all such matters has been negative inasmuch as ours is a purely scientific meeting extending a mere three days and the need for such entertainment has not arisen. Perhaps the Executive Committee will like to reconsider this matter at this time.

A number of years ago the Petroleum Research Corporation of Denver asked for permission to reproduce on micro-cards or micro-films papers published in the *Transactions* relative to the Rocky Mountain region. This was granted in 1953 covering the *Transactions* through 1953, with the arrangement to continue until June 30, 1955. They now ask extention of this to cover *Transactions* through 1957. It is recommended that this request be granted.

Plans seem to be developing slowly for the establishment of an Institute of Geophysics at the University of Hawaii. The initial sum proposed for this is now two and one-half million dollars instead of one million dollars originally suggested. This is a much more realistic figure.

The U. S. National Commission for UNESCO is holding a conference in San Francisco, November 6–9, 1957, and has asked us to designate representatives. We have requested three members (Robert C. Bundgaard, J. W. Johnson, and N. Allen Riley) in the San Francisco area to represent the AGU.

The Second International Conference on Peaceful Uses of Atomic Energy will be held in Geneva, September 1–13, 1958. The U. S. Atomic Energy Commission has invited AGU to submit names of authors, titles, and abstracts. If approved, they would be submitted to the Secretary-General of the United Nations.

A. NELSON SAYRE,
General Secretary

Action on recommendations in the General Secretary's report—There was discussion of the Russian translation project, it being noted by Harry Hess that there is a new project afoot in England to prepare international abstracts to cover the entire field of geophysics. It was agreed that we should take steps to see that this is correlated with our own endeavors. It was also agreed that payment to Pergamon Press for work on the Russian translation project should be on the basis of proof of performance. It was noted that about 150 answers to our questionnaire about the translation project had been received, most of these indicating their willingness to cooperate in giving us reactions to this effort as the project proceeds, in return for which they are to receive a copy of the abstract journal as it is issued. It was planned to build this list to about 500 addresses.

It was agreed that C. A. Oficina Technica de Obras Maritimas of Venezuela was a proper candidate for corporation membership, the question having been raised because of the fact that they are outside of the United States.

It was noted that President Ewing has designated Walter M. Bucher and James R. Balsley, Jr. to serve as our representatives on the Board of Directors of the American Geological Institute.

It was noted by Harry Hess that the bill for the establishment of an Institute of Geophysics at the University of Hawaii has not yet been acted upon by Congress.

Henry R. Joesting noted that the International Geological Congress has established an International Geological Abstracting Service for the abstracting of foreign publications and that Earl Ingerson has been designated as the United States representative on a committee to look into the possibility of securing National Science Foundation aid in this.

Reports of Standing Committees

Audit—Chairman A. G. McNish presented the report of the Committee covering the fiscal year ending June 30, 1957, which was accepted (see Appendix 1). It was noted that, in accordance with Executive Committee instructions, excess funds in our checking account have been transferred to an interest-bearing savings account in the Riggs National Bank. This savings account is currently $40,000. The Executive Committee agreed that this had been appropriately deposited.

International Participation—Chairman J. W. Joyce commented with respect to the Eleventh General Assembly in Toronto, outlining the various problems presented there including the revision of the Statutes and By-Laws. Because of the statutory requirements relative to these changes, they were necessarily based upon the draft circulated by the General Secretary of IUGG in the spring of 1957 and could not incorporate some of the principles that were presented in our own later draft which were looked upon as involving changes that did not meet statutory requirements with respect to time. The changes involved an enlarged Bureau of IUGG consisting of the President, two Vice Presidents, General Secretary, and three members at large (instead of the President and General Secretary as at present). Membership categories were revised, which will result in an increase in U. S. dues from £1500 per year to £3000. The General Assembly set up a committee for the further consideration of changes in the Statutes and By-Laws, and it is anticipated that there will be further changes in 1960. The new changes have the effect of improving continuity in the actions of IUGG, noting that the new Bureau is to meet in Paris on December 2–7, 1957, with plans to meet at least once a year in the interim until the next General Assembly in 1960.

There is the expectation that the agenda for the next General Assembly will be circulated to the various National Committees well in advance of the meeting in Finland in order to avoid the state of confusion that currently occurs in early meetings of the Council and the Executive Committee.

With regard to the representation of Germany and the Republic of China, it was urged that the scientists of these two countries attempt to get together to work out common representation in the IUGG. This seems immediately possible in the case of Germany. With respect to Cuba, a committee is to be appointed to determine what group in Cuba may most appropriately be representative of geophysics in the IUGG.

Representatives of the Sections to each of the Associations made brief reports relative to the Toronto meeting (these in general largely reviewed details which have already been covered in the report on the meeting published in the December 1957 issue of the *Transactions*, pp. 984–987).

Charles A. Whitten noted that the complete reports for the Association of Geodesy will appear in *Bulletin Geodesique* and that plans have been made to hold five international symposia during the next three years, including one in the United States on electronic surveying to be held in March 1959.

In Meteorology, Jerome Namias noted that the Association of Meteorology has decided to publish only the abstracts of the papers presented, recognizing that there are now a great many outlets for meteorological papers. He also stated that there was lively discussion concerning the use of the word "Aeronomy" by the Association of Geomagnetism and Aeronomy.

With regard to the Association of Geomagnetism and Aeronomy, J. Hugh Nelson noted that the sessions were excellent, especially the symposium on aeronomy, and that the Association took no steps to make further change in its name.

A. Nelson Sayre noted that the meetings of the Association of Hydrology were well attended, especially those relating to subterranean waters, and that there is great variability in the quality of the papers. Thomas Maddock noted that there was discussion of the tendency for interest in Association activities to drop off in the intervals between meetings and that to overcome this two symposia have been arranged for the interim, one relating to snow and ice and another to forests and water.

In the Association of Oçeanography, John Lyman noted that many of the American papers were excellent and that the isotope tracing technique is being looked upon as increasingly valuable in tracing ocean waters. He reported that the French are doing much on the optics of sea water. He urged that the matter of representation at all sessions in subsequent meetings should be carefully worked out. It was also noted that steps need to be taken to clarify certain difficulties in connection with the work of the Association of Oceanography. The Executive Secretary was directed to proceed to Seattle in connection with his trip to the regional meeting at Pullman to consult with Richard H. Fleming on this matter if it cannot be resolved otherwise.

In the Association of Seismology and the Physics of the Earth's Interior, Leonard M. Murphy noted that the group in geochemistry was seeking an outlet either through Volcanology or this Association, but was not sure how things would work out. He also noted that there were many high-quality papers, including a number from the USSR, that participants in the Association's meetings from the USSR were very cooperative, and that in this Association the matter of the feasibility and cost of drilling a test hole through the Mohorovicic discontinuity got its impetus.

J. Frank Schairer noted that the Association of Volcanology had a very active meeting but that there were no programs prepared in advance. It was agreed by the Association to establish four sections to include active volcanoes, volcanophysics, physical chemistry of magmas, and paleovolcanology and plutonism, with geochronology included.

With regard to the meeting in Toronto, Chairman Berkner indicated that President Ewing had requested him to raise two questions based on the experience at that meeting, (1) regarding the composition of the U. S. National Committee and (2) the matter of national reports for the various Associations. In general, it was felt that there should be some measures taken to review papers originating in the United States before being presented, and that in one or two cases failure to do this resulted in rather embarrassing situations. It was recommended that the whole matter of U. S. participation should be reviewed by the Committee on International Participation based on this experience, especially as there is likely to be considerably more activity between the Assemblies, and to see to it that the activities are appropriately monitored in the Associations and to make sure that the papers presented are of a satisfactory quality. A specific report should be made on these points in May 1958.

The matter of national reports before the various Associations also requires consideration. In some instances very complete printed reports were available for the various Associations. This requires long advance planning and, of course, involves also the principles in this connection desired by the Associations Proper reports would be quite voluminous and involve a good deal of work. It was thought that the reports should essentially be summaries of research, noting that the Canadians now put out a volume which summarizes their research for the year and that this plan might be followed.

It was noted that certain changes in the Statutes and

By-Laws were effected at the time of the meeting in Toronto and a continuing committee will work on this matter with the expectation that there will be further modification in 1960.

A meeting of the new Bureau of the IUGG is to be held in Paris in December 1957. It is expected that there will be a discussion of the new IUGG Chronicle, plans for the publication of symposia, and other material in a continuing professional journal in international geophysics. A geophysical bibliography will presumably also be discussed. The sentiment was strongly against IUGG undertaking the publication of a scientific journal. The abstracting problem, it was felt, had best be worked out in a commercial enterprise, but there is need for such a worldwide journal which might well dovetail into the work in which AGU is now engaged under a National Science Foundation grant. In connection with the organization and publication of symposia, the Chairman noted that: (1) Symposia must be carefully organized by sound leaders and the papers must be really representative of the progress in the field for subsequent publication with discussion as an integrated volume; (2) the symposium should have an editor appointed in advance to put them into proper form; (3) the International Union should make arrangements with a publisher to publish them on a commercial basis, not as an IUGG publication; (4) the symposia should be appropriately indexed; (5) they should be published promptly. The suggestion of the establishment of awards in geophysics to be undertaken by IUGG was not encouraged. It was felt that the Bureau, at its meeting in December, should look thoroughly into the financial situation of IUGG.

The Executive Committee recessed for lunch at 12h 45m, with a second session called to order at 13h 45m.

Editorial and Publication—Chairman Sayre noted that the Committee had met every two months, that the backlog is building up again, and that there has been some criticism that the contents of the *Transactions* are too heavy on the hydrologic side as compared with other phases of geophysics, perhaps because of the fact that in the broad sense hydrologic papers find their chief outlet in the *Transactions*.

There was discussion of the thought that the *Transactions* and the *Journal of Geophysical Research* might be joined and that this might become a monthly journal representing the circulation of both publications with a scientific editor and an editorial board of which only the scientific editor would receive compensation. This should be a balanced journal and provide a rapid place for persons to get first-rate articles into prompt publication. The journal should also include one review article each month; reprints of these can then be assembled under a single cover as a monograph if this seemed desirable. It was suggested that the modified journal be called the *Journal of Geophysical Research*, with a note at the bottom "Combined with the *Transactions* of the American Geophysical Union." It was noted that the flow of hydrologic papers is not likely to decrease but rather increase because of the increasing demands on our water resources. It was agreed that the President should appoint a committee to go into this matter thoroughly including financial and other arrangements, recognizing that it would probably take some outside support during a transition period and also involve an increase in dues.

The Executive Committee approved granting permission to the Petroleum Research Corporation of Denver to reproduce on micro-cards or micro-films the papers published in the *Transactions* relative to the Rocky Mountain region as an extension to the arrangement made earlier.

Nominations—Chairman L. H. Adams offered no formal report, but it was noted that all Sections should be alerted to activate their Nominating Committees in order that these may function during the winter and spring and shortly after the annual meeting in May 1958 be prepared to offer their formal slates of nominees in accordance with our regular nominating procedures.

Statutes and By-Laws—In the absence of Chairman K. Hilding Beij, it was noted that certain changes in By-Laws were approved at the Executive Committee meeting on April 28, 1957 [see p. 608 of the August 1957 *Transactions*]. Thus changes in By-Laws having now been published the required period of time are out for final action. The Executive Committee confirmed its action of last spring subject to the approval by the membership and the National Research Council of the appertaining Statutes. It was noted that certain changes in the Statutes are pending and that a ballot would be sent out soon. These are likewise set forth in the August 1957 issue of the *Transactions*, page 608.

Meetings—Chairman P. H. Abelson noted that the programs are set up by the Sections and that, since primarily only three Sections are involved in the IGY activity, those Sections might be encouraged to develop a symposium for the Annual Meeting next spring. It was noted that Chairman Vestine of the Special Committee on Cosmic-Terrestrial Relationships has talked about a symposium in this field and that Joseph Kaplan, the new President of the International Association of Geomagnetism and Aeronomy, had arranged a symposium on aeronomy at the meeting in Toronto which was outstanding and that there might be a further development of this. Chairman Abelson plans to get into touch with the various Section Chairmen to work out specific programs. The question was raised by the Executive Secretary whether it is felt we should alter in any way the general character of our meetings and whether we are putting too much emphasis on the division of geophysics into sections rather than on its integration. It was expressed by Chairman Berkner that perhaps our meetings in Washington should develop themselves more to general symposia, with the development of particular phases at national meetings in various locations outside of Washington. It was suggested that the Chairman of the Committee on Meetings feel out the membership on this matter and that possibly steps be taken to rotate national meetings in various locations either on a voluntary or on an invitation basis. It was agreed that planning is necessary.

Membership—Chairman Earl G. Droessler noted that the membership campaign is proceeding well. Appendix 2 is a formal report that he presented in summary, which was accepted. It was agreed that we should approve C. A. Oficina Tecnica de Obras Maritimas of Venezuela as a corporation member.

Budget—Chairman John C. Reed presented the interim report of the Committee as given in Appendix 3, which was accepted. It was noted that because of an increase in printing charges it may be necessary for us to draw on our limited reserve to the extent of as much as $5000 for the current fiscal year. The increase in publication costs is just about $5000, and an increase of $1.00 per member for dues would defray that. It was agreed, however, that we should not raise dues at this time but work instead on increasing the membership and securing more advertising. The matter of a per-page charge was discussed, and it was agreed that this matter should be studied by the new committee appointed to study the matter of combining the *Transactions* and the *Journal of Geophysical Research*, perhaps following the policy of the *Journal of Geophysical Research* and the *Physical Review*.

In connection with the Russian translation project, no overhead is now being charged, and it was agreed that we should enter into negotiations with the National Science Foundation to secure the customary 15 per cent to cover this project.

Reports of Special Committees

Award of William Bowie Medal—Chairman Walter H. Bucher reported that after a series of letter exchanges the Committee met in Toronto and selected J. Th. Thijsse as the twentieth recipient. In line with the policy adopted last spring, this is to be announced at this time and plans laid for an informal dinner and the publication of a four-page program. The folder as outlined by the Chairman will have an announcement of the bestowal on the first page, the second page will be a summary of the recipient's achievements, the third page will list the previous Bowie medalists, and the fourth page will contain the principles of bestowals of the Bowie Medal. The report was accepted.

The question was raised as to whether the William Bowie Medal can be awarded posthumously and, if so, that this might be a fitting honor to bestow upon C.-G. Rossby. There was general concurrence that posthumous awards should not be undertaken.

Advertising—Chairman N. C. Gerson was not present, but it was noted that on the basis of his report advertising rates were increased effective with the August issue. The basic rate is now $250 per page per issue.

Cosmic-Terrestrial Relationships—Chairman E. H. Vestine was not present, but note was made of the suggestion that he undertake the arrangement of a symposium in connection with the meeting next spring.

Tellers—It was noted that this Committee, under the chairmanship of J. H. Nelson, will soon have a task to perform in connection with the ballot on the changes in the Statutes.

Education in Geophysics—Harry H. Hess reported that he had met with Chairman John E. Nafe, who is setting up plans to proceed.

Reports of Sections

Volcanology, Geochemistry, and Petrology—The Paricutin films compiled by the late William F. Foshag are in need of editing and some general work. President J. Frank Schairer is looking into this problem and feels that AGU might go to the National Science Foundation to secure a small grant in order that these films may be put into proper shape and then perhaps placed in the film library of the Library of Congress.

National Research Council Reports

International Relations—Director Wallace W. Atwood, Jr. reported that there will be a General Assembly of ICSU in Washington, September 26–October 7, 1958, and that on November 23, 1957, there is to be a general meeting at which plans will be laid for this Assembly.

Earth Sciences—Chairman Harry H. Hess presented a summary of the report that appears as Appendix 4. This was accepted.

Affiliated Organizations

American Geological Institute—It was noted that James R. Balsley, Jr. and Walter H. Bucher have been appointed as AGU delegates on the Governing Board of the American Geological Institute.

New Business

Meeting of U. S. National Commission for UNESCO at San Francisco, November 6–9, 1957—AGU has been requested to send representatives to this meeting, and certain persons have been asked to serve. It was noted by Chairman Berkner that at the last meeting of ICSU a resolution was circulated pointing out that the Natural Sciences Division of UNESCO is getting less and less of the total of the UNESCO budget so that the situation is becoming critical. Inasmuch as ICSU obtains support on particular projects from UNESCO it is important that, if the situation offers, our representatives to the U. S. National Commission meeting should support this resolution. The Office of International Relations was requested to supply the necessary information.

International Geophysical Year—A report of a special committee appointed by Joseph Kaplan, Chairman of the U. S. National Committee for the IGY, with respect to what happens upon the close of the IGY, was presented. The report sets out that certain aspects of the IGY should be continued and that the Academy should take steps to see that this is given direction. This proposal was endorsed.

Adjournment—The meeting adjourned at 16h 45m.

A. Nelson Sayre, *General Secretary*
Waldo E. Smith, *Executive Secretary*

Appendix 1—Report of the Committee on Audit for the Fiscal Year Ending June 30, 1957

A. G. McNish, Chairman
E. B. Roberts R. H. Weightman

Your Committee on Audit has examined the books of the American Geophysical Union for the fiscal year ending June 30, 1957, and finds them in agreement with the statement of the Union's finances supplied by the Executive Secretary.

At the beginning of the current fiscal year the cash assets of the Union amounted to $41,895.32, including Series F bonds valued at purchase cost and deposits in the Permanent Fund. In addition, bills receivable were estimated at $7,183.18 and liabilities amounted to $3,564.89, leaving a surplus of $45,513.61. At the close of the present fiscal year the cash assets of the Union amounted to $80,832.25, including the abovementioned bonds and investments, with an estimate of bills receivable of $11,954.97 making the total assets of the Union $92,787.22. Liabilities including bills payable amounted to $43,799.76, leaving a surplus of $48,987.46. Approximately half of the cash assets and liabilities are due to the Russian Translation Project, for which funds have been received in the amount of $40,900 subject to expenses which will be incurred by the Union in prosecution of the project. Operating expenses of the Union during the past fiscal year exceeded income by $2,043.77, which is due in part to rental of quarters for the first year by the Union and in part to an increase in the cost of printing the *Transactions*.

Your Committee has examined the evidence of these assets which support the report of the Executive Secretary. Our report is not based upon a completely detailed audit of all financial transactions of the Union but on a careful examination of certain essential aspects to give the Committee complete confidence in the soundness of this report.

Your Committee wishes to compliment the office of the Executive Secretary for the excellent state in which the accounts of the Union are kept, all details being subject to documentary verification.

Operating Statement

(Fiscal year ending June 30, 1957)

Receipts			
National Research Council grant			$400.00
Income			
Dues, 1954 and earlier	$238.17		
1955	396.33		
1956	4,098.04		
1957	32,536.17		
1958 et seq	133.95		
Corporation Memberships	2,500.00		
Life Memberships	300.00	$40,202.66	
Sales of publications			
Transactions	$12,580.77		
Reprints	3,923.99		
Geophysical Monograph No. 1	7,733.85[a]		
Miscellaneous	43.60	24,282.21	64,484.87
Contributions to Permanent Fund			253.00[a]
Interest on Permanent Funds			419.95
Contribution to T. M. and E. Award Fund			250.00[a]
Interest on T. M. and E. Award Fund			37.52
Interest on deposit with Interstate Building Association			364.11[a]
Russian Translation Project			40,900.00[a]
Advertising receipts			5,667.46
American Geological Institute			19.22[a]
Sale of equipment (3 fans and 2 Dazor lamps)			97.00[a]
Miscellaneous			158.82
Total receipts			$113,051.95

Disbursements		
Publishing *Transactions*		
Printing	$23,138.07	
Preparing copy	7,757.65	
Honoraria to editors	1,312.50	
Mailing	1,177.86	
Advertising expense	2,317.85	$35,703.93
Reprints		2,033.34
General expenditures (office of the Union)		
Salaries (including Federal Social Security)	$18,320.43	
Stationery and supplies	1,341.01	
Postage and communications	1,384.48	
Office equipment	19.90	21,065.82
National Academy of Sciences pension plan		1,062.56
Expenses, Committee on Membership		40.00
Expenses, Committee on Advertising		17.25
Expenses, Section of Meteorology		15.00
Expenses, Section of Hydrology		17.00
Expenses, Meetings		
Annual Meeting	$1,423.24	
Regional Meetings	51.31	1,474.55
Investment: Deposited in Liberty Building Association, part of T. M. and E. Award Fund		250.00[a]
Investment: Deposited in Prudential Building Association, part of Permanent Fund		560.00[a,b]
Geophysical Monograph No. 1		6,218.04[a]
Rent		3,672.31
Legal services ($130) and audit costs ($300) for zoning appeal)		430.00[a]
Directory		2,119.36
Russian Translation Project		169.30[a]
Bowie Medal		14.00
President's fund		56.20[a]
Miscellaneous		6.36
Total disbursements		$74,925.02

[a] Non-budget items.

[b] This is actually a transfer of funds; the amount remains available to AGU.

Excess of disbursements over receipts

Disbursements (including transfer of $560 to Permanent Fund)	$74,925.02	
Adjustment for transfer	560.00	
Net disbursements		$74,365.02
Receipts (including special fund for Russian Translation Project)	$113,051.95	
Less balance in special fund for Russian Translation Project	40,730.70	
Receipts, regular AGU funds		72,321.25
Decrease in liquid funds, regular account		$2,043.77

Statement of assets and liabilities as of June 30, 1957 (see p. 143 of Feb. 1957 *Transactions* for statement of assets and liabilities as of June 30, 1956)

Assets		
Cash Reserve		
On deposit in Riggs National Bank	$54,625.02[a]	
On deposit in Interstate Building Association	9,864.11	$64,489.13
Permanent Fund		
Series F bonds purchased prior to July 1, 1948 (maturity value $3,200), at cost	$2,368.00	
On deposit in Northwestern Federal Savings and Loan Association as of July 1, 1957	9,770.15	
On deposit in Prudential Building Association as of July 1, 1957	1,916.87	14,055.02
Forwarded		$78,544.15

Brought forward			$78,544.15
Emergency Fund			
On deposit in Prudential Building Association as of July 1, 1957		1,000.00	
T. M. and E. Award Fund			
On deposit in Liberty Building Association as of July 1, 1957		1,288.10	2,288.10
			$80,832.25
Bills Receivable			
Dues			
1957 only	$3,992.00		
1956 and 1957	3,055.00	$7,047.00	
Publications			
Transactions (including back numbers)	$2,744.24		
Subscriptions	270.00		
Reprints	1,140.47		
Miscellaneous	28.27

Advertising	337.16	4,907.97	11,954.97
			$92,787.22
Liabilities			
Bills Payable and advance payments			
Dues in advance (1958 et seq.)	$135.65		
Subscriptions in advance (1958 et seq.)	312.00		
June 1957 *Transactions*, balance due about	2,500.00		
Misc. (mainly credits a/c overpayments)	121.41	$3,069.06	
Russian Translation Project commitment		40,730.70	$43,799.76
Surplus (Capital Account)			48,987.46
			$92,787.22
[a] Riggs National Bank statement of June 30, 1957			$58,178.19
Less checks outstanding			3,553.17
			$54,625.02

Appendix 2—Membership Committee Report

The AGU membership campaign is proceeding with increasing momentum. We now have five outstanding section leaders appointed and all of them are working hard to bring in more new members.

The work of Elliot B. Roberts, Chairman of the Government Members Section, merits special note. He has received an enthusiastic response to his letter-writing campaign, he has been able to appoint AGU keymen in 60 different government agencies spread throughout the U.S. The keymen, through staff conferences, office circulars, and by personal contact are spreading information on the AGU and are recruiting new members. Recently we received a sheaf of 13 new membership proposals from one AGU keyman, A. M. Moore, Assistant District Engineer, Geological Survey, Portland, Oregon.

Another section leader whose outstanding work merits special mention is Willis B. Foster, Chairman of the Publicity Section. He has prepared two new very attractive and informative brochures which we printed in number. One brochure will be sent out to prospective student and regular members, and the other is for soliciting new corporation members.

Ben F. Howell, Jr. Chairman of the University Members Section, has launched his program, and with the opening of the school year he will extend it to cover all students and teachers in geophysics. Chairman Howell will ask a faculty member to sign up student members for the AGU at each of the schools offering courses in geophysics. In looking to the future, this is one of the most important elements in our membership drive, a large body of student members today will be regular members of tomorrow.

The Chairman of the Commercial and Industrial Members Section, Nelson Steenland, has only recently been able to devote his attention to the task of enlarging the list of AGU corporation members. He has a supply of the new brochures and other material, and expects to be in full operation soon.

Paul A. Smith has taken over chairmanship of the Membership Qualifications Section. He has begun to draft new criteria covering qualifications for the membership classes of the AGU. Any recommendations in his report will come before the Executive Committee at some future meeting.

EARL G. DROESSLER, *Chairman*

Appendix 3—Interim Report of the Committee on Buget for the Fiscal Year Ending June 30, 1958

J. C. Reed, Chairman
E. H. Bramhall L. O. Quam

This interim report comprises an analysis, as of October 1, 1957, of the American Geophysical Union budget for the fiscal year ending June 30, 1958 as presented to the Executive Committee last May and as approved by that Committee.

At the May meeting, the Executive Committee indicated that it would like the Budget Committee to expand its responsibility to include advice in financial matters to the Executive Committee. This has been discussed by the Budget Committee and none of its members feels qualified to give substantive advice in such matters. Some discussion was held as to the desirability of obtaining professional advice from a bank or other authority. The Budget Committee requests more direction from the Executive Committee in this matter. Incidentally, since the May meeting, a savings account in the amount of about $40,000 has been opened, from which the Union should derive a little more interest than was previously estimated. The amount of the savings account will vary from time to time as funds are needed or not needed for current operations. A substantial part of the funds used to open the savings account was from the National Science Foundation for the translation responsibility and did not appear in the budget approved last May.

In the budget report approved in May, the receipt of $3000 from the sale of excess copies of the *Transactions* was anticipated. The item was not included in the budget because it was not known whether the money would be received in the 1957 or in the 1958 fiscal year. The funds, in the amount of $2400, have now been received and can be entered in the receipts column for the 1958 fiscal year.

Estimated Receipts

Item	Original budget estimate	Actual, 7/1–10/1	Estimate, 10/1–6/30 (based on actual in past fiscal year	Present estimate
National Research Council grant	$400	..	$400	$400
Membership dues	43,300	$2,996	36,671	39,667
Sales and subscriptions	12,000	1,096	11,140	12,236
[Monograph receipts, not previously budgeted]	..	398	602	1,000
Reprints	4,000	1,310	3,168	4,478
Advertising	6,000	2,964	4,370	7,334
Interest[a]	820	..	1,422	1,422
Miscellaneous	500	15	143	158
(Sale of *Transactions*, not previously budgeted)	..	..	2,400	2,400
	$67,020	$8,779	$60,316	$69,095

[a] Because of interest expected from the new savings account, this item has been increased $600 over the figure that otherwise would be estimated at this time. This was based on an assumed average of a savings account of $20,000 earning interest at 3 percent.

Estimated Expenditures

Item	Original budget estimate	Actual, 7/1–10/1	Estimate, 10-1–6/30 (based on actual in past fiscal year)	Present estimate
Transactions				
Preparation of copy	$7,900	$1,807	$6,133	$7,940
Printing[a]	24,000	8,961	18,778	27,739
Mailing	1,200	307	969	1,276
Editors	1,350	. . .	1,313	1,313
Advertising costs	2,500	59	1,717	1,776
Reprints	2,200	410	1,778	2,188
General Office expenses				
Rent	3,720	932	2,877	3,809
Salaries & social sec.[b]	17,000	4,758	14,177	18,935
Retirement contribution	1,050	266	797	1,063
Stationery and supplies	1,500	78	1,013	1,091
Postage and comm.	1,500	394	1,207	1,601
Equipment	500	19	20	39
Annual meeting	1,000	25	1,423	1,448
Regional meetings	100	. . .	29	29
Section expenses	100	. . .	11	11
Committee expenses	100	9	57	66
Travel	1,000	. . .	1,000	1,000
Directory reserve	1,000	. . .	1,000	1,000
	$67,720	$18,025	$54,299	$72,324

[a] Increase due to increased rate for printing.

[b] Increase due to some extra help used during summer and to fact that Union has been carrying some salary time expected to be carried by National Science Foundation funds for translations.

There follows a comparison of receipts and expenditures as estimated in the budget approved in May with the same items as estimated now.

From the above, it will be seen that receipts may amount to $2,075 more than earlier estimated and expenses may be $4,604 greater. As the earlier estimate indicated a deficit for the year of $700, the present estimate indicates a deficit of $3,229.

The committee greatly appreciates the assistance of the Executive Secretary in supplying the required data and in advising the committee.

Appendix 4—Report of the Union's Representative to the NRC Division of Earth Sciences 1956–1957

Your representative attended all meetings of the Executive Committee of the Division of Earth Sciences during the year (Oct. 13, Dec. 8, 1956, and Feb. 2, Mar. 30, April 27, 1957), all meetings of the Governing Board of the NRC and the annual meeting of the Division.

The following items of general or specific interest to the Union are culled from the year's activities of NRC division of Earth Sciences.

(1) (Meteorology) The Committee on Climatology Advisory to the Weather Bureau continued to function efficiently.

(2) (Hydrology) The Committee on Radioactive Waste Disposal on Land Advisory to AEC completed a report covering two years of its operation. This will be distributed by NRC before the end of November.

(3) (Oceanography) A conference to explore the needs for research in the field of oceanography was held on Feb. 19, 1957 in Washington. An outgrowth of the conference was the naming by President Bronk of Harrison Brown as chairman of a Committee on Oceanography. The field of interest of this committee will be somewhat broader than that of our Section of Oceanography inasmuch as it will include biological problems and conservation. Your representative urged the appointment of such a committee inasmuch as several of the most interesting fields of research in this area had suffered from lack of government liaison since the demise of the RDB panel on Oceanography.

(4) (Volcanology) A Conference on Basalts was organized for the day of the annual meeting of the Earth Science Division. The conference was most successful. Seventy-five people attended.

(5) (Volcanology) With the help of a small grant from NSF a conference on Tektites was held in Washington on June 17–18. About 30 scientists attended the meeting and considerable progress was made in defining the problems Tektites present and in indicating possible solutions.

(6) (General) The Proceedings of the Convocation at Woods Hole (June 22–24, 1954) were published as a volume of the Journal of Marine Research dated Dec. 31, 1955 but actually distributed in the summer of 1956. The volume contains many excellent papers relating to geophysics.

(7) (Meteorology, Oceanography) A Conference on Arctic Sea-Ice is to be held in February 1958.

(8) (Tectonophysics, Seismology) The Executive Committee of the Division sent a letter of congratulations to George Woollard on his achievement in getting seismographs into position on short notice to observe the recent underground nuclear explosion. The observations were made in Mexico at 18° and 20° from the explosion site.

Your representative would like to comment that much of the Division of Earth Sciences' activity has been in the field of geophysics in the last few years. It is most important for the Union to maintain close and cordial contact with NRC on the working level. By doing so the science of geophysics can be advanced and this should be our major objective.

H. H. Hess

Pacific Northwest Meeting Held in Pullman, Washington, October 28–30, 1957

The Fourth Pacific Northwest Regional meeting was held jointly with the Washington State College Hydraulics Conference at Pullman, Washington, on October 28–30, 1957. The joint sessions served to bring together the theoreticians and practical field men. An estimated 50 regional members of the Union attended the various scientific sessions, with actual attendance exceeding 100. Waldo E. Smith, Executive Secretary of the Union, was in attendance and spoke on certain aspects of the Union activities, including editorial policy and the status of the *Transactions*. A meeting of the Regional Committee was held on October 29. Wilbur D. Simons (409 Federal Building, Tacoma 2, Washington) was selected as Chairman for the year beginning July 1, 1958, and Vail Schermerhorn (320 Custom House, Portland, Oregon) as Secretary-Treasurer for the same period. It was decided to hold the 1958 meeting in Portland, Oregon. A business luncheon was held for the regional members on October 29, at which Milton S. Sachs addressed the group on the September meetings of the IUGG in Toronto.

Special Announcements

Thirty-Ninth Annual Meeting, Washington, D. C., May 5–8, 1958—Last-minute attention is called to the previous announcements regarding this meeting published in the *Transactions*, particularly that of October 1957, pages 797–798, relating especially to the program, and that of December 1957, page 989, bring-ng program matters up to date and giving information egarding hotel rooms.

The details of the program are rapidly being settled, nd in some Sections, notably Meteorology, the pro-ram is closed as noted in the December announcement. he programs for all other Sections close March 5. hree copies of titles and abstracts for these Sections hould be in at the latest by March 5. Keep abstracts rief and informative, giving concise results rather than n outline of the paper. Indicate projection equipment eeded and the amount of time desired (ordinarily 0–20 minutes are allowed).

Symposium on Snow and Glaciers—A symposium entitled "The Physics of Ice Movement" will be held by the International Association of Hydrology, IUGG, in Chamonix, France, September 16–24, 1958. Those interested in the symposium in the United States should get into touch with Ralph N. Wilson, Secretary of the Section of Hydrology, AGU, and those from other countries with their respective National Committees or with the Secretary of the International Association of Hydrology, L. J. Tison, 61, rue des Ronces, Gentbrugge, Belgium.

IGY BULLETIN

A monthly survey by the U. S. National Committee for the International Geophysical Year. Established by and part of the National Academy of Sciences, the Committee is responsible for the U. S. International Geophysical Year program in which several hundred American scientists are participating and many public and private institutions are cooperating.

Oceanographic Expedition Downwind

Bulletin No. 2 described briefly some of the objectives of the IGY Deep Water oceanographic program and some pre-IGY work in the Atlantic Ocean. Many institutions in the United States and other countries are participating in this work.

Another major IGY cruise in the Pacific, expedition "Downwind," got under way on October 21, 1957, when two vessels, the *Horizon* and the *Spencer F. Baird*, left San Diego, California, for the central and south Pacific. These research vessels are operated by the Scripps Institution of Oceanography, La Jolla, California.

Earlier Cruises

Previous Scripps expeditions have covered much of the north Pacific through the waters south of Alaska, to Japan, and back. The central Pacific regions, from Hawaii to the Marshall Islands, southward to Fiji and Tonga, and back via Samoa, the Society Islands, the Tuamoto Archipelago and the Marquesas Islands, have also been visited. The "Midpac" cruise of 1950, during which the mid-Pacific submarine mountain range was explored, worked predominantly in the region from 15°N to 40°N. The "Capricorn" expedition of 1952–53, a joint operation by the *Horizon* and *Baird*, lasted five and one-half months and reached about 26°S.

During these previous expeditions, much work related to the present IGY oceanographic program was done. Extensive seismic refraction profiles were completed. In such operations one ship, the listening ship, lays to with hydrophones in the water while the other, the shooting ship, runs a line of seismic shots starting about 50 miles away from the listening ship. The shooting ship drops TNT charges ranging in size from several hundred pounds at the extreme limits of the line to one pound near the listening ship. This technique of exploration of the submarine crust has been used throughout most oceanic areas. Much effort has been devoted to study of the submarine crustal structure in areas of geologic interest, such as trenches, island arcs, fracture zones, isolated marine mountains, some of the great plateau areas, and undersea rises.

Other activities included in these expeditions are: taking cores of the bottom sediments; heat flow measurements through the sediments; surface current measurements with the geomagnetic electrokinetograph (GEK); deeper current observations with drogues; Nansen bottle casts for chemical studies and to obtain density data for use in calculating deep currents; underwater photography for study of marine life; drag and grab samples of the bottom in unsedimented areas; photographs of the bottom for geologic and biologic purposes; detailed bathymetry of trenches, sea mounts, and other features of topographic interest; observations of the magnetic field with towed magnetometers; and many kinds of marine biological work.

Downwind

The Downwind expedition will make most of the geophysical observations listed above as part of the IGY program to map the deep circulation of the oceans. The approximate track of the expedition is shown in Fig. 1. Oceanographic ships of Canada and the *Brown Bear* of the University of Washingto have covered areas north of the Scripp tracks as part of the plan to observe th currents in a long meridional profile. Ship of other countries, notably Australia, Ne Zealand, Japan, and Russia, have worke and are working in other areas of the Pacifi as part of the IGY plan to obtain extensiv coverage.

The leaders of the expedition are Henr W. Menard, Jr., and Robert L. Fishe

f the Scripps Institution. The scientific arty includes geologists, marine biologists, eismologists, chemists, oceanographers, and hree physicians. J. N. Nanda, Chief cientist of the Navy of the Republic of ndia, two Argentine, two Chilean, and two eruvian scientists are expected to particiate in the Valparaiso-to-Callao leg of the ruise.

bservational Program

During the Downwind expedition about 0 hydrographic casts will be made using ansen bottles and reversing thermometers; pecial samples will be taken for analysis of adioactive isotopes. Seven groups of bottom hotographs will be taken using an undervater camera developed by the U. S. Navy lectronics Laboratory.

A special probe developed at Scripps will e used at about 33 locations to measure eat flow through the oceanic sediments (only a small number of such measurements re now available). Heat flow data are useful n studies of crustal thickness and can also e applied to the study of the deep currents. During the Capricorn expedition, in 1953, he heat flow on the Albatross Plateau was nexpectedly high. This single measurement vill be checked by revisiting the general area. f heat flow for oceanic rises proves to be igher than for basins or trenches, it would end weight to suggestions that convection urrents in the earth's interior might be esponsible for tectonic effects at the crust.

These heat flow measurements are only part of the program of exploration of the marine crust. The cruise will establish the submarine topography of a profile along the 130°W meridian from the latitude of San Diego to about 50°S. About 15 dredge hauls will be made to collect samples as part of a study of the mineral resources of the sea floor, and almost 100 sediment cores are planned. Considerable attention will be devoted to a study of a most unusual topographic feature, the Tuamotu Archipelago. This group of atolls rises about one mile above the broad submarine ridges on which they stand. The ridges themselves are about a mile and a half higher than the deep sea floor. Twenty-five seismic profiles are planned, with emphasis in this and other areas of special geologic interest, such as the Easter Island Rise and the narrow, deep Andean Trench just off the coast of Chile and Peru. The relief from the bottom of this trench to the top of the adjacent Andes is the greatest in the world.

Progress

H. W. Menard has summarized the work accomplished in the first two weeks of the expedition in a radio message to Scripps. He reported the following: nine deep hydrographic casts made; twenty-four sediment cores taken; three dredge hauls made; twenty-six seismic reflection stations and two seismic refraction stations occupied, including one using a small boat for shooting; 162 bathythermograph observations made; four bottom photographs made; and twenty seamounts discovered, six of which have been surveyed in detail. The program for assay of CO_2 in the air and in sea water has been essentially continuous.

Menard describes some interesting results of these early observations. The four bottom photographs, at depths between 13,200 and 14,400 ft, are the deepest yet obtained in the Pacific. They all show evidences of biological activity, such as trails, mounds, holes, or a pavement of manganese nodules, depending on sediment type. Seismic reflection shots show sediments 984 ft thick at 20°N, thickening to 1640 ft at the equator. A seismic refraction run at the equator revealed normal sound velocity in the sediments and deeper layers. A piston sediment core contained 33 ft of recent calcareous ooze, but the heat conductivity measurement was surprisingly low—0.4 microcal/cm^2/sec. The daily averages of atmospheric CO_2 have ranged from 312 to 310 ppm.

Brief stops for refueling or local scientific investigation are scheduled at Papeete, Tahiti; Easter Island; Valparaiso, Chile; and Callao, Peru. The expedition will last about four and one-half months and will cover almost 40,000 miles of track.

Expedition Vessels

As the La Jolla location does not permit berthing of seagoing vessels, the ships of the Scripps fleet are docked at the Navy Electronics Laboratory facility at Point Loma, contiguous to San Diego harbor.

The two vessels, *Horizon* and *Spencer F. Baird*, are converted 143-ft ocean-going tugs; they are steel-hulled, single-screw, diesel-electric vessels, with displacement of 934 tons and draft of 16′5″ when loaded. The *Horizon* was acquired by Scripps in 1947, the *Baird* in 1951. The two ships have identical hulls but differing superstructures, and have been converted with somewhat different design.

The laboratory space on each ship is about 600 square feet. Each carries a crew of 17 and accommodates up to 15 in its scientific party.

For both ships, two twelve-cylinder Diesel engines driving separate direct-current generators and exciters supply power for two electric motors geared to a single shaft. The normal cruising speed is 11 knots with a range of about 10,000 miles. Food and water storage capacity allows about 45–50 days at sea between ports of call.

The after-decks or fantails of both ships are quite roomy; most equipment is lowered over the side from platforms either at the stern or at the side of the fantail immediately abaft the maindeck laboratory. Large A-frames have been constructed at the stern of each ship to handle the heavy and sometimes very bulky instruments. The A-frame of the *Horizon* rises about 28 ft from the deck. The main 35-hp winch is capable of handling 20,000 ft of $\frac{1}{2}$-inch wire. Other winches include a hydrographic winch with 20,000 ft of $\frac{3}{16}$ wire, a bathythermograph winch, and a special winch for electric cables, such as those used for the GEK and Thermitow instruments. The *Horizon*, usually the seismic shooting ship, has space for magazine storage of about 24 tons of explosives.

The A-frame on the *Baird*, with a platform about 35 ft above the fantail, is designed to handle loads of 20 tons. Her heavy winch, one of the three largest oceanographic winches in use today, is of the winding-machine type with electro-hydraulic drive and about 100-hp capacity. It is mounted immediately abaft the main deck laboratory. In conjunction with a storage reel mounted on the deck below, the winch handles up to 40,000 ft of tapered steel cable varying from $\frac{3}{8}$ to $\frac{3}{4}$ inch in diameter, and a shorter auxiliary cable of $\frac{1}{2}$-inch diameter. Two bathythermograph winches and two power-driven gypsies complete the power equipment on the fantail. On the boat deck are mounted two hydrographic winches, with capacities of 20,000 and 30,000 ft of $\frac{3}{16}$-inch wire. The *Baird* also has magazine storage space for explosives, and, as it is the listening seismic ship, the laboratory is equipped with seismic amplifying and recording equipment. A darkroom has been fitted out for immediate development of records and film.

Both ships are equipped with sonar, radar, considerable communications apparatus, loran, and echo sounders of both conventional type and newer precision models. The *Baird* also carries radio facsimile equipment.

Polar Ice and Snow Studies

The following article is based primarily on material supplied by Henri Bader of the US Army Snow, Ice, and Permafrost Research Establishment.

The major portion of the IGY effort in the field of glaciology is directed toward the study of ice and snow in the polar regions, particularly their glaciers and ice sheets. These studies will give information not only on the behavior of ice and snow under polar conditions but will also yield data on climate.

Two thirds of the area of the Greenland ice sheet and practically all of the Antarctic ice sheet are permanently dry. All precipitation is in the form of snow. Summer melt is rare and usually affects a surface layer only a few centimeters thick. Thus every snowfall, including everything that falls with it, is separately and safely filed away for future reference under later snowfalls.

The first man literally to dig into the 'files' was Sorge of the Wegener Expedition. At Eismitte in the center of the Greenland ice cap in 1930–31, he dug a 15-meter pit, counted the annual snow layers, and determined their density. During the past few years the records of the snow layers in Greenland have been examined in more detail and at greater depths by means of methods and instruments developed mainly by the US Army Snow, Ice and Permafrost Research Establishment (SIPRE).

Sorge's researches gave rise to a qualitative statement of the relationship of snow density, time, and climate. Sorge's Law is: At any given location in the dry snow region of a glacier, the density of the snow as a function of depth does not change with time unless the climate changes. SIPRE has given mathematical form to Sorge's Law and is expanding it to include the effects of changes in rate of precipitation and in temperature.

Snow is a poor conductor of heat; therefore, the amplitude of temperature variations in snow diminishes rapidly with depth. In Greenland the temperature at ten meters depth is almost constant and is within one degree of the mean annual air temperature. Thus, measuring the snow temperature at this depth gives important climatic data without the necessity of long-term meteorological observations.

By digging a pit, counting annual layers, and measuring snow density as a function of depth below the surface, the amount of annual precipitation for many years can also be determined. The usual procedure involves digging a pit several meters deep, measuring temperature and noting stratigraphy in the pit wall, and taking closely-spaced samples with standard ½ liter tubes for density measurements. For samples from greater depths, a hole is sunk from the bottom of the pit with a hand-operated core drill.

The identification of annual layers can be difficult unless there are thin ice crusts or other features to aid in distinguishing summer from winter layers. In Greenland it is possible to count annual layers almost without error, but in the Antarctic, there is much less precipitation and summers are much colder; therefore, the layers are thinner and not always characterized by ice crusts resulting from summer melt. It may be impossible to identify summer layers at high altitudes. A method of distinguishing between winter and summer layers by reason of the differing ratios of oxygen isotopes 16 and 18 in the snow has been developed by Samuel Epstein of the California Institute of Technology, but this method requires extensive laboratory work.

The tritium content of the snow can be used to estimate its age but only for snow which fell prior to 1954. Since then, hydrogen bomb tests have upset the natural tritium balance. Analysis for other radioactive contaminations in precisely dated snow layers in Greenland and in Antarctica will yield data on general atmospheric circulation since the first fission bombs were exploded in 1945. It should also be possible to follow the degree of atmospheric contamination resulting from industrial activity by analyses of snows down to the layers which fell in preindustrial times.

Natural substances which fall with the snow and are buried beneath succeeding layers—such as volcanic ash, meteorites, spores, and bacteria—are extremely well preserved. Ash from the 1912 eruption of the Alaskan volcano Katmai was easily identified in a snow layer at a depth of 32 meters below the 1954 snow surface at a point 200 miles east of Thule, Greenland. It is doubtful that this 1912 deposit, which is almost certainly continuous over the whole of Greenland, will be found in the Antarctic, but the ash of the 1883 Krakatoa eruption may prove to be identifiable in both hemispheres.

The deepest penetration into the past during the IGY is planned for the US deep drilling program which has been entrusted to SIPRE. In preparation, SIPRE, in 1956, drilled to 300 meters at its experimental station on the Greenland ice sheet. Core recovery was very incomplete, the primary objective being the development of drilling techniques. A modified Failing "1500" drill rig and especially designed core barrels are used for this work. Ice cuttings are removed by compressed air which has been cooled so as to prevent melting of the core or the wall of the hole.

In the summer of 1957 SIPRE drilled a still deeper hole at the same Greenland site, reaching a depth of 411 meters. Almost all cores were recovered to a depth of 300 meters but beyond that depth only two cores were brought to the surface intact, one from approximately 360 meters depth and one from 400 meters.

Core recovery from such depths is difficult because, as the snow is compressed under the load of overlying layers, its permeability decreases. At a density of approximately 0.83 the ice becomes impermeable, and with further densification the air in the enclosed bubbles is compressed. When the pressure of the overlying snow reaches 20 kg/cm^2 at a depth of 230 meters, the bubble pressure is 14 kg/cm^2, equal to the tensile strength of ice. Drilling releases the confining pressure, causing both the core and the ice forming the wall of the hole to crack. Cracking becomes worse with increasing depth.

The cores from the Greenland drilling have not yet been analyzed completely but annual layers of snow have been identified to the year 1700, ±10 years, and the age of the deepest core is estimated to be approximately 800 years. In Northeastern Greenland and in Antarctica, where the annual accumulation is much smaller, depths of 300 meters will include 2000 years of frozen history.

Other glacial pit studies and deep core drilling for the IGY program are already underway in the Arctic and Antarctic. Glacial pits have been dug at all the major US stations in the Antarctic. The deepest to date is the pit at the Wilkes Station which was sunk to a depth of 35.25 meters with a drill hole at the bottom of the pit extending another 27 meters.

Part of the equipment required for deep core drilling was delivered to Byrd Station by tractor train on October 24, 1957. The remainder will be delivered by air in the near future. Drilling will start as soon as the equipment is ready.

Other stratigraphic studies will be made by the European International Glaciological Expedition to Greenland, the Canadian Expedition to Northern Ellesmere Island, the US party at the McCall Glacier in the Brooks Range in Alaska, and by other nations at Antarctic stations.

Rocket Flare Patrol Program

Valuable data on solar X-rays during solar flares were obtained during July and August using rockets launched from San Nicolas Island, within the US Navy Pt. Mugu Range, sixty miles off the California coast. The rocket launchings were part of the DAN Rocket Flare Patrol Program, which is designed to determine the radiation source of the radio fadeouts caused by flares on the disk of the sun.

This IGY rocket program was conducted by the Electron Optics Branch of the Naval Research Laboratory (NRL) under the supervision of Herbert Friedman, and with the assistance of T. A. Chubb, J. E. Kuperrian, Jr., R. W. Kreplin, and J. C. Lindsay.

Flare-Upper Atmosphere Relationships

X-rays and Lyman-alpha radiation are two possible sources of the increased ionization responsible for radio fadeout conditions.

X-ray emission from a quiet sun arises in the million-degree coronal gas and consists of recombination continua and line emissions from all the atoms of the coronal atmosphere in their various states of ionization. In an ionization equilibrium at one million degrees Kelvin, the M shells of all atoms are stripped, corresponding to ionization potentials of several hundred electron volts (ev), or wavelengths of 20–100 Å. (The innermost shell of an atom, containing two electrons when filled, is designated the "K shell"; the "L shell," with 8 electrons when filled, lies next to the K shell; and the "M shell," containing at most 18 electrons, is next to the L shell). If the temperature of a local coronal condensation is increased to five million degrees Kelvin, the K shells of the lighter elements up to oxygen may be ionized, corresponding to ionization energies of the order of 1500 ev, or wavelength of about 8 Å. A much greater rise in temperature would be necessary to bring about the excitation of the K shells of Fe atoms. Such temperatures may be produced in flares. The series limit for the K shell of Fe is 1.4 Å. The abundance of elements heavier than Fe in the solar atmosphere is too small to contribute appreciably to the net X-ray flux. A limit to the X-ray spectrum arising from thermal excitation of the corona may therefore lie in the neighborhood of 1.4 Å for all flares larger than a certain critical magnitude. The rocket discovery of 1–2 Å X-rays in a typical Class 3+ flare implies that the wavelength limit is almost reached by such flares.

In support of the above hypothesis are the observations of Sudden Phase Anomalies (SPA). The SPA is a measure of the drop in the base of the D-region reflecting layer for long radio waves in the earth's upper atmosphere. A maximum drop of 16 km never appears to be exceeded in a wide variety of Class 3, 3+, or even in the rare cosmic ray flares. This height difference of 16 km is of the same order of magnitude as the difference in theoretical depth of penetration of the atmosphere by Lyman alpha ultraviolet rays and X-rays in the 1- to 1.5 Å range. Lyman alpha is responsible for normal D-region ionization. Although an increase in Lyman alpha may account for part of the increased D-region ionization during a flare, it cannot produce the very low-level ionization observed in the SPA. In order for Lyman alpha to produce a16-km drop in the base of the D region, the total solar Lyman alpha intensity would have to increase by a factor of 10^4. Since the flare region occupies at most 10^{-3} of the disk, the implication is that Lyman alpha in the flare region increases to 10^7 times the normal value. Such a flux density is virtually impossible astrophysically. X-ray flares can readily account for the magnitudes of observed depressions in the reflecting base.

Radio absorption measurements during Sudden Ionospheric Disturbances (SID) require a five to tenfold increase in total ionization in the absorbing region for Class 2 and 3 flares. The observed X-ray fluxes are adequate to produce such increases in electron density.

Scientific Results

The scientific results of the program to date are of considerable interest. New geophysical data on solar X-rays have been obtained for flares of Class 1+, 2, and 3+ magnitudes, as well as background data under no-flare conditions. From preliminary inspection of the telemetered data certain features of the X-ray emission are quite clear. A flare produces a marked increase in X radiation of short wave length, or hardening of the X-ray spectrum, compared to that of the quiet corona. The largest flare produced the shortest wavelength X-ray emission, about 2 Å. The total X-ray flux varied from about 10^{-3} ergs/cm^2/sec for the Class 1+ flare to about 10^{-2} ergs/cm^2/sec. for the Class 2 flare. An estimate has not yet been made of the flu in the Class 3+ flare but it appears tha hardness of the spectrum may play a mor important role than total flux in accountin for the associated SID.

In every case, an attempt was made t time the rocket firing with the expecte maximum phase of the flare. In each firing therefore, the first few minutes of flar development were by-passed. No evidenc has been obtained for large increases i Lyman alpha during any of the flare firings However, this does not justify ruling ou the possibility of a Lyman alpha flash ver early in a flare.

Field Operations

The field operation of the DAN Flar Project is of considerable interest as it con- trasts with other rocket launching opera-

Table 1. *Summary of Results of Rocket Flare Patrol Program*

IGY Rocket No.	Date	Altitude (feet)	Sun	Data	Comments

* Orientation of rocket with respect to sun.

ions. Except for the first few launchings, the ield crew has consisted of five to seven men. This crew has been made up partially of personnel from the NRL Optics Division and artially of employees of the Cooper Development Corporation (CDC), contractors o NRL. The NRL crew handled the preparation and installation of the rocket instrument heads, the monitoring of information from the solar observatories, the onitoring of radio fadeout, the firing of he rockets, the telemetering system, and he field analysis and interpretation of the data. They also made auxiliary photographic records of the rocket launchings in the interest of advancing the development of techniques for handling small rockets. The CDC field crew handled the preparation of the two-stage rocket, that is, fitting the crated Nike booster and Deacon bottles with fins and junction fittings, adjusting the rocket fins with spin tabs, preparing Deacon igniters, installing Deacon and Nike igniters, mounting the rockets on the launching frames, operating the launcher, and handling the repeated arming and disarming of the rockets during the daily operations of the group.

In the course of the program, several advances in the technique of using small rockets for research purposes have been accomplished. A new type of aerodynamic telemetering antenna, with uniform radiation pattern, was developed and gave perfect telemetering performance on all flights. Extensive data on the yaw behavior of small rockets above the restraining influence of atmospheric stabilization have been obtained. The effect of using no second-stage closure (NACA system) on ignition delay and subsequent rocket yaw has been observed and photographed, and a closure system for the two-stage trajectory configuration has been developed. The practicability of command firing of small rockets with only a 60-second delay has been proven. The practicability of rapid repeated firing of small research rockets from a single rocket launcher has been confirmed. Measurements of skin temperature were made. Data were accumulated on the effect of rocket yaw on altitude. Boosters have been visually tracked and some experimental information on the influence of wind on the rocket's trajectory is available. Much detail on rocket behavior is contained in the telemetering records yet to be analyzed.

The success of this project was made possible by the cooperation of the Navy personnel at Pt. Mugu, California. Cdr. O. E. Hearn, USN, designed the launching site and was responsible for all arrangements with the Navy for carrying out the project. The correlation of scientific rocket results with direct solar observations was made possible through the cooperation of Sacramento Peak, High Altitude Observatory, and Mt. Wilson personnel, who observed the sun through the long hours of the rocket operation and maintained the difficult communication links with the island.

Microcard Program for IGY Meteorological Data

The following article is based on material supplied by D. A. Davies, Secretary-General, World Meteorological Organization, Geneva, Switzerland.

The IGY Meteorological Data Centre, in the World Meteorological Organization, is publishing on microcards the essential meteorological data collected during the 18 months of the International Geophysical Year.

Microcards are standard-size library catalogue cards (75 x 125 mm, 3 x 5 inches) on

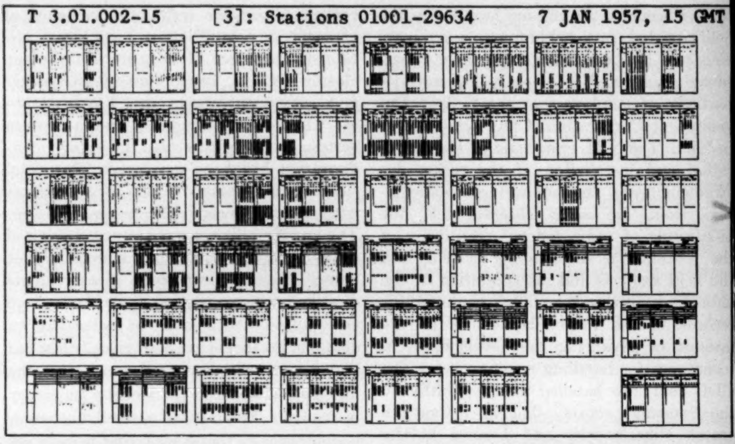

Fig. 2. *Typical WMO Microcard Used in IGY Meteorological Program (actual size 3" x 5").*

which a number of the original forms (40 to 96) are reproduced in greatly reduced size (see Fig. 2). A special microcard reader, which projects an enlarged image onto a tilted screen, is used for reading the data.

A complete set of microcards of IGY meteorological data consists of four parts, corresponding to the four different types of standard forms on which the essential meteorological data are being recorded. They are:

Part 1. Synoptic Surface Observations—Land Stations (Form No. 1)
Part 2. Synoptic Surface Observations—Sea Stations (Forms No. 2 and No. 2(b)
Part 3. Radiosonde and Rawinsonde Observations (Form No. 3)
Part 4. Upper Wind Observations (Form No. 4)

Description of the Four Types of Microcards

Form 1, Synoptic Surface Observations—Land Stations, contains 20 surface observations made at a single station during a period of five consecutive days (i.e., one pentade) at the synoptic hours 0000, 0600, 1200, and 1800 GMT. Each Part 1 microcard has room for a maximum of 96 reproductions of Form 1 arranged in eight rows of 12 forms each; however, the number of forms reproduced on any one microcard will vary between 70 and 90 in order to leave sufficient space for headings, additions, alterations, etc. The forms will be assembled according to the WMO station index numbers. Twenty-five microcards will accommodate the data from 2,000 surface stations; the surface synoptic observations recorded on Form 1 during the 110 pentades of the IGY will, therefore, require a total of 2,750 microcards.

Synoptic surface observations made at sea stations are being recorded on two variations of Form 2. Ships' reports will be written or typed on the basic Form 2, while on the other, Form 2 (b), they will be tabulated from punch cards. Forms containing observations made on board ships at the same synoptic hour will be published together on one or more microcards. It is estimated that about 4,400 Part 2 microcards, reproducing Forms 2 and 2(b), will be sufficient to publish all synoptic surface observations made at sea stations during the IGY.

Radiosonde and rawinsonde observations

re recorded on a standard form, Form 3, hich may contain the results of three or our ascents. Microcards on which these orms are reproduced, constituting Part 3 f the set, have room for 40 to 48 forms ar-anged in five or six rows of eight forms ach. Ascents made at the same standard ime will be grouped according to the WMO tation index numbers.

The largest of these groups in Part 3 will onsist of microcards reporting daily ascents ade at 0000 and 1200 GMT throughout the GY. Five to six microcards will probably e needed for each of these two main ynoptic hours, making a total of 5,500 icrocards for the whole of the IGY.

Reports of ascents made daily at 0600 and 800 GMT will be reproduced in another, maller group of about 220 microcards.

Additional ascent data gathered on Regu-ar World Days and in World Meteorological ntervals will be reproduced in a third group f about 280 microcards.

The total number of microcards on which adiosonde and rawinsonde observations ill be reproduced (Part 3) will, therefore, pproximate 6,000.

Upper wind observations are recorded n a standard form which has space for 10 bservations. The microcards on which these orms are reproduced, Part 4 of the set, ave room for 40 to 48 forms arranged in ive or six rows of eight forms each. Ascents made at the same standard time will be grouped in the sequence of the WMO station index numbers, preserving as far as possible the same basic regional layout for each of the four main standard times—0000, 0600, 1200 and 1800 GMT—during the whole of the IGY. Microcards containing upper wind data collected during the IGY (Part 4) will total about 5,000.

Complete Set of WMO Microcards for IGY

It is estimated that about 18,500 microcards (including a small margin for possible additions, etc.) will be required to reproduce the essential meteorological observations to be made during the IGY. These are distributed among the four basic data groups as follows:

Part 1—2,750 microcards
Part 2—4,400 microcards
Part 3—6,000 microcards
Part 4—5,000 microcards

A subscription price of $5,990 has been established for one complete set of the microcards. Prices for partial sets and individual microcards will be announced at a later date. Orders for microcards may be placed with the World Meteorological Organization, IGY Meteorological Data Centre, 1 Avenue de la Paix, Geneva, Switzerland. Further information about them may also be obtained from this address.

Ionospheric Studies Using Earth Satellites

A conference on study of the ionosphere by means of radio observation of earth satellites was held on November 5, 1957, at the Central Radio Propagation Laboratory (CRPL) of the National Bureau of Standards, Boulder, Colorado. Organized by the USNC-IGY, under the direction of A. H. Shapley, the conference brought together groups that had spontaneously initiated ionospheric experiments utilizing radio transmissions from satellites launched by the USSR.

The purpose was to enable these groups to discuss their progress, explore refinements in experimental techniques, plan future observations, and discuss problems of reduction and interpretation of measurements made with the first satellites.

Table 2. *Observation of Soviet Satellite Signals*

Agency	Signal Strength Data	Doppler Data	Interferometric and Other Phase-Difference Data	Direction Finding and Radar Data
BRL		20 mc; 0.1–1% slant range accuracy	Two 20-mc interferometers in plane of orbit	
Caltech	20, 40 mc; on tape	20, 40 mc		
DTM			40-mc phase-switching interferometer data for $\alpha 2$, from Oct. 4; also for β	
Geo. Inst.	20, 40 mc with WWV, from Oct. 4		40-mc total-power interferometer	
HAO	20 mc, 65 passes; on tape (12 in first 24 hours of $\alpha 2$)	20 mc; satisfactory data for 20 passes	20-mc total-power interferometer, Oct. 4–18	
Linc. Lab.	20 mc, Oct. 5–25; 40 mc, Oct. 6–25; exact measurement of frequencies	20, 40 mc; accuracy 2 secs in time, 10 miles in slant range		Radar with 2° x 2° beamwidth; same DF data taken at first; vertical incidence ionospheric soundings
NBS	20 and 40 mc, E-W and N-S; 100 cycle/sec recorder; low angle 40-mc rhombic antenna data; pulse studies	20 mc, 40 mc; calibrated against WWV: accuracy several cycles/sec	Phase-switching interferometers: 40-mc E-W, and 20-mc E-W (double baseline); 40-mc N-S total-power interferometer; continuous phase recording on 1000-ft. baselines; 20, 40 mc, E-W and N-S, circularly-polarized antennas	
Los Alamos	Tape records of $\alpha 2$, β	40 mc data using human ear discrimination; 3% accuracy in slope		
NEL			Data from Oct. 5 on N-S & E-W sets of 2 spaced antennas; MK I minitrack adaptation: 20-mc N-S and E-W signal recordings; 40-mc N-S and E-W phase recordings	
NRA			2 dipole E-W interferometers	
NRL		Some data obtained	Minitrack (in operation at Blossom Point, Lima, and San Diego); null times at 20 mc, continuous phase recording at 40 mc; WWV recorded on traces	Radio-telescope altitude data
ASEL and ASRPA	Data from Oct. 4 (aural Oct. 4–7)	Records for Oct. 6–8 at Fletcher's Ice Island, Oct. 8–9 at Thule, Oct. 6–8 on Grand Bahama Island, from Oct. 6 at Adak		Precision 20 and 40 mc; precision DF data from Oct. 5
SRI	20 and 40 mc from Oct. 4 on tape with WWV	Some 20-, mostly 40-mc data from Oct. 4; slant ranges; simultaneous Doppler observations of data		DF: 40-mc for more than one week; 106-mc radar observations
U of Ill.	20 mc on tape, Oct. 4	A few tapes	40-mc records from Oct. 5: N-S (5.45λ spacing), N-S (1λ), and E-W(6λ); 20-mc N-S (5.45λ) continuous from Oct. 6; N-S data on highspeed instrument to record detailed fading

Observations Reported

Representatives of some 24 laboratories and organizations were present at the conference. As an introduction to further discussion they were asked to give short accounts of their observations of the first two satellites, designated $\alpha 2$ and β. Table 2 presents very briefly a résumé of the experiments reported by those participating.

At the time of the Boulder conference, radio transmission from satellite $\alpha 2$ had ceased, but the conference date fell in the middle of the one-week period of transmission from satellite β. Consequently, the entries in the table refer primarily to studies of satellite $\alpha 2$, although in most cases the indicated observations were continued during the period of activity of β.

Signal strength data, as listed in Table 2 include times of appearance and disappearance of radio signals during individual satellite passes. These differ for the two frequencies of signals used. In accordance with theory, under ordinary conditions waves of both frequencies penetrate the ionosphere, but the higher-frequency waves should traverse the ionosphere at greater angles of incidence than those of the lower frequency, and should, therefore, be observed for a longer period of time at ground level. However, this theoretical behavior is actually found to be greatly modified by skip and by anomalous effects not understood at present. The signal levels themselves have been found to be subject to fluctuations, as explained below.

The Doppler effect (col. 3 of Table 2), is well known as the decline in pitch of a railroad train's whistle as the train flashes past the observer. As observed from a fixed ground station, the corresponding decrease in satellite radio frequency during a pass is not only a function of the velocity and position of the transmitting satellite relative to the receiver, but also, according to theory, it is to some degree a function of the ion density along the path between satellite and observer and in the immediate environment of the satellite itself. Hence, interest in such measurements is great.

Typical Doppler curves for $\alpha 2$, recorded at the National Bureau of Standards' Boulder Laboratories, are shown in Fig. 3. The more abrupt the curve, the closer the satellite passed the site of the receiver. Ionospheric effects are also contained in such curves, so that, conversely, if the satellite oscillator is stable and the precise orbit of the satellite is known, ionospheric densities can be deduced from the Doppler shifts. Useful Doppler observations need not be too involved since the human ear functions to excellent advantage in determining the general nature of such curves.

The principle of comparison of phases received over different paths as a means of position determination has been described in some detail in an article on Minitrack equipment in *Bulletin No. 2, August 1957*. Such interferometric observations (col. 4 of Table 2) are subject to fading or fluctuation effects and especially to refraction by

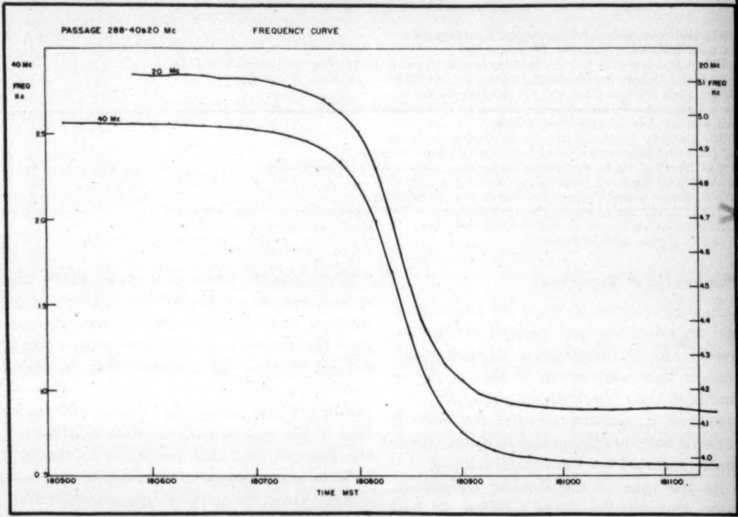

Fig. 3. *Doppler Effect at Table Mesa Site, National Bureau of Standards, Boulder, Colorado, on 288th Passage of Satellite 1957 α2 October 23, 1957.*

the ionosphere. Sometimes, so-called total-power interferometers have been used to subtract the fading effects introduced along the transmission path or caused by changes in the relative orientation of the satellite and the observing antennas. In this way, phase variations can be studied separately, without the hindrance of extraneous fluctuations. Interferometric measurements can also be very useful in determining the nature of the upper ionosphere, for, if a precise orbit is known, deviations from expected behavior may be attirbuted to specific ionospheric phenomena.

In Table 2 are listed radar installations and direction finding instruments. The latter provide data based on signal intensities received at different bearings. (A 400-mc, narrow-beam radar in operation at the Geophysical Institute, University of Alaska, is not listed; no satellite data were obtained there owing to lack of a sufficiently precise satellite-search ephemeris.) Radar observations of the final phase of satellite orbits would be especially useful. Integrated ion concentrations along radar paths can be deduced from the Faraday effect (rotation of the plane of polarization in the presence of a magnetic field). Thus, the hitherto unknown ion concentrations above the F2-layer maximum can be deduced if knowledge of the ionospheric structure below that level is available.

Although not all of the fifty or more persons participating in the conference had experimental data to summarize, a number of unusual events were reported.

—H. W. Wells of the Department of Terrestrial Magnetism, Carnegie Institution, reported the reception of strong 40-mc signals when the satellite was on the opposite side of the earth. He stated that the half-transit "ghosts" were clean signals and could not have been caused by an occasional cloud or sporadic-E propagation.

—R. M. Gallet of CRPL reported a

sudden decrease of 500 cycles/sec in the basic 40-mc transmission frequency of $\alpha 2$ at the time of the 250th pass, on October 21.

—Louis Burkhardt of Los Alamos noted that a decrease of about one kc in the 40-mc signal of $\alpha 2$ had occurred just before final fadeout. The fadeout itself was observed by several participants to have been gradual rather than abrupt.

—F. R. Dickson, of the Army Signal Radio Propagation Agency, indicated that during one 24-hour period there was continuous reception of satellite transmissions at Adak. (All *passes* during one such period were observed at the IGY South Pole Station.) Dickson also noted anomalies in DF records that appeared to be auroral in origin.

—Doppler frequency curves are sometimes distorted. Some curves plotted at the High Altitude Observatory were reported by D. Billings to have shown a lower maximum rate of decrease than would be consistent with initial and final rates of decrease. This is attributed to ionospheric effects. C. G. Little stated that one out of ten Doppler records at the Geophysical Institute, University of Alaska, shows distortion. Little and W. O. Roberts of the High Altitude Observatory agreed that frequency reversals of Doppler data are seen occasionally, although those observed in Alaska seem to be associated with auroral transmission and occur for only a second or two rather than as long as a minute.

The most general and significant problem of record analysis discussed was that of fluctuations and fading rates. R. N. Bracewell reported that amplitude records at Stanford showed faint CW transmissions between "beeps" received from $\alpha 2$ at long range. He also noted that in order to deduce ionospheric characteristics from observational records, fading owing to such mechanical factors as satellite spin or attitude would necessarily have to be extracted so that the influence of such factors as rapid auroral fluctuations or variations resulting from the Faraday rotation could be assessed. R. Jastrow of the Naval Research Laboratory, L. G. de Bey of Ballistics Research Laboratory, and R. S. Lawrence of CRPL, reported on the wide variety of phase and amplitude fluctuations observed. J. Herbstreit stated that continuous phase recordings with spaced antennas are potentially valuable for studying ionospheric turbulence. It was noted that some preferred periodicities seemed to be about 1½ sec and 4 or 4½ sec. It was pointed out that antenna polarities and orientations are such that a very subtle analysis of the records is required to arrive at a proper interpretation.

E. Hayden of the University of Illinois stated that observations frequently began with scintillations, which later changed to regular fading, leaving one-sec fluctuations superposed on a four-sec rate. Fade periods rapidly decreased as the satellite passed out of range. On 20-mc interferometer records, precursor fluctuation patterns were often observed in the afternoon before the actual interference pattern appeared. W. O. Roberts, of the High Altitude Observatory, stated that HAO records also showed such behavior, but in the opposite order. On some evening passes signal strength increased as the satellite receded, according to W. S. MacDonald, of the California Institute of Technology. It was agreed that maximum signal strength is not useful as an indication of time of closest approach.

Suggestions and Recommendations

Considerable discussion at the conference concerned the role radio amateurs might play in satellite observations. In general, it was felt that the observation of in and out times, rough signal strengths, and perhaps Doppler observations—preferably with a common, general, standard-reference frequency—might be useful, particularly in connection with long-range propagation effects. It was informally suggested that George Grammer, who was present as representative of the Amateur Radio Relay

League, might formulate the precise program. Amateurs would be asked to perform their own data reduction but the ARRL might act as a clearing house to accept and examine their reduced data.

Participants at the conference asked IGY satellite-tracking organizations to indicate the kinds of supplementary data which would be useful to them. They also requested that orbital and prediction data be distributed widely, rapidly, and in a form readily usable at each station; it was desired that precision estimates accompany the data. Observers were themselves asked to submit comparisons of satellite prediction and observation to the Smithsonian Institution and the Naval Research Laboratory.

The need for simultaneous optical and radio satellite observations was emphasized; any data fixing the orbit more precisely is helpful in extracting ionospheric information. Simultaneous ionosonde and radio observations would also be most useful. It was strongly urged that satellite transmission frequencies be stabilized as much as practicable to permit the extraction of the maximum quantity of ionospheric information from precision Doppler data. The desirability of having some future satellite transmissions at frequencies of the order of 20 mc, with known modulation as a control experiment, was recognized by all. There was also an extended discussion of the comparative usefulness of Doppler and Minitrack observations for obtaining orbital data.

NATIONAL ACADEMY OF SCIENCES

IGY BULLETIN

A monthly survey by the U. S. National Committee for the International Geophysical Year. Established by and part of the National Academy of Sciences, the Committee is responsible for the U. S. International Geophysical Year program in which several hundred American scientists are participating and many public and private institutions are cooperating.

First Sea Surface Gravimeter

The first successful surface measurements of gravity in the open sea were made on November 22, 1957, by J. Lamar Worzel, Assistant Director of the Lamont Geological Observatory at Columbia University, using a new sea gravimeter developed by Anton Graf of Munich. The instrument was mounted on a gyro-stabilized platform installed aboard the USS *Compass Island*. (The *Compass Island*, one of the few vessels on which a stabilized platform is installed, was made available for this work by Captain L. L. Schork of the U. S. Navy's Bureau of Ordnance.)

Gravity values for ocean areas have, in the past, had to be measured in submarines submerged to quiet depths. Difficulties in obtaining and fitting submarines for this purpose greatly restricted the accumulation of gravity data for the 80 percent of the earth's surface that is covered by water. The new sea gravimeter now makes it possible to take gravity measurements simply and expeditiously in moderately calm seas any place on the ocean surfaces of the earth, thus assuring that data long needed but difficult or impossible to obtain will now be available.

To date there have been only about 5000 measurements of gravity made at sea throughout the world. A device for multiplying the volume of such data is therefore of the greatest importance for the objectives of the IGY gravity program. This program seeks (1) to fill in the major gaps in a world gravity network, principally in the Arctic, Antarctic, and ocean areas, and (2) to relate existing networks, generally national in character, to each other so as to produce a first-order international network. Attainment of these objectives will greatly improve gravimetric mapping, which offers the fastest and most accurate method for linking all maps to a common reference system, and add much to knowledge of the earth's shape and the distribution of its mass.

Roughly half of the existing sea surface gravity measurements have been made by the Lamont Geological Observatory in the past 10 years, using pendulums carried in submerged submarines. Gravity measurements at sea were begun as recently as 1927 by Vening Meinesz, who developed a pendulum apparatus for use on the spongy soil of Holland. Meinesz found that his pendulums could be used in submarines to take gravity readings in the open sea, and it was he who made most of the 1,200 oceanic gravity measurements recorded by the end of World War II. Since the end of the war, British and Dutch scientists, in addition to those at Lamont, have conducted submarine gravity programs.

The new sea surface gravimeter has additional advantages over the standard submarine pendulums. Surface gravity measurements from the USS *Compass Island* were

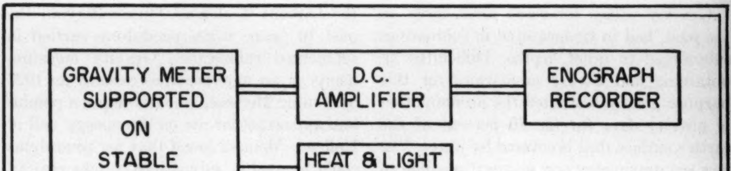
DIFFERENTIAL PHOTOCELL
OUTPUT

Fig. 1.

taken in nine hours, as compared with two days for earlier submarine measurements of comparable areas. The data were reduced in just one-half day, as compared with two weeks needed to adjust and compute data from submarine measurements.

The USS *Compass Island* left New York November 18 and returned November 22. To evaluate the accuracy of the Graf sea gravimeter, which had previously been tested on a surface ship only on a lake and the Adriatic Sea, the surface measurements were begun 200 miles southeast of New York on November 22, at a point where measurements had been taken aboard the submarine USS *Tusk* in 1947. The surface measurements were continued on a track which closely duplicated the *Tusk's*, moving from the deep ocean basin across the continental slope and onto the continental shelf, ending off Fire Island, New York.

The Graf sea gravimeter consists of a



GRAVITY METER SUPPORTED ON STABLE PLATFORM
D.C. AMPLIFIER
ENOGRAPH RECORDER
HEAT & LIGHT POWER SUPPLY

Fig. 2.

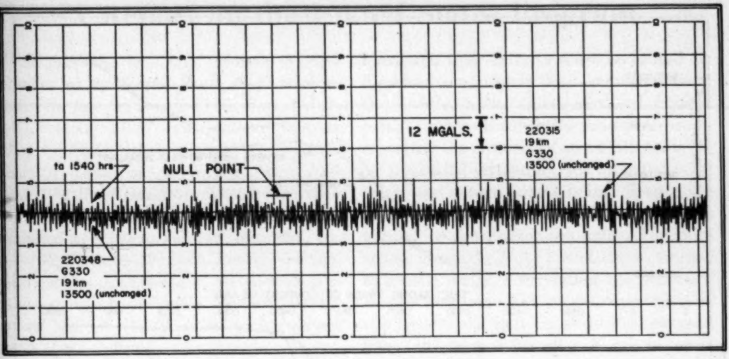


Fig. 3.

horizontal aluminum boom sprung and pivoted on horizontal cylindrical springs near one end (see Fig. 1). The position of the boom is determined by a differential photocell which is activated by a lamp illuminating a slit attached to the boom. The field of a large permanent magnet is cut by the aluminum boom, providing eddy current damping when the boom moves. The small instrumental volume results in air pressure compensation. The system is largely temperature-compensated; it is enclosed in a doubly-thermostated oven maintaining the temperature within about 0.01°C.

Figure 2 is a block diagram of the system. The output of the gravimeter is amplified in the d.c. amplifier, further damped electrically, and then recorded on an Enograph recorder, a self-balancing potentiometer-type recorder.

The operation of the equipment consists of establishing the meter on the stable platform and levelling it. The springs are adjusted to bring the boom close to the instrument null point, as indicated by the Enograph recorder. The wave accelerations appear as fluctuations of the recorder trace about a mean position. The damping of the overall system is such that wave accelerations with periods of six seconds are reduced by a factor of 10,000, and wave accelerations with periods of ten seconds are reduced by a factor of 3000. The time constant of the highly-damped system is such that a change of gravity requires five minutes for its complete registration.

The dial reading at the null point is computed from the dial setting combined with the mean position of the boom indicated by the recorder. The scale constant of the meter and observations at base points permit one to calculate the gravity reading for each five- to ten-minute section of the record.

Certain types of corrections are made for each observation. The ship has a centrifugal acceleration owing to the rotation of the earth; it is necessary to make a correction (the Eötvös correction) of this acceleration because of the east-west component of the ship's speed. Later, the effects of current can be estimated from the ship's navigation plot. The resultant observed gravity is then available for such anomaly computations as desired.

Figure 3 shows approximately a one-half hour section of the record made on board USS *Compass Island* The wave periods were about eight seconds and maximum vertical accelerations of 140,000 milligals peak to peak are indicated as about 20 milligals peak to peak on the record.

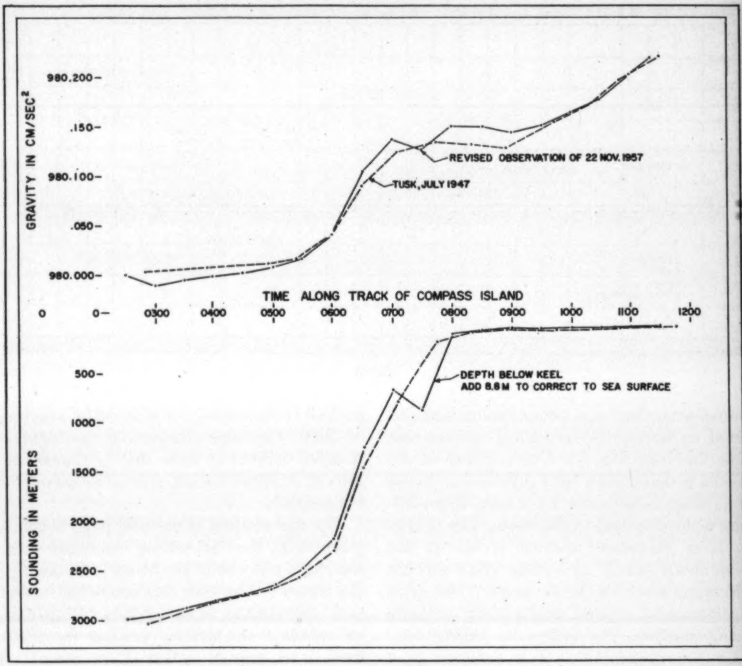

Fig. 4.

Figure 4 shows a plot of the observed gravity values at half-hour intervals on USS *Compass Island* and the observations of USS *Tusk* projected to the track of USS *Compass Island*. The bottom half of Figure 5 shows the corrected soundings obtained on each ship at the same time that the gravity readings were made. The comparison of these data is considered extremely satisfactory in view of the differences in the observation positions and the much poorer navigation data accompanying the USS *Tusk* observations with respect to both position determination and the Eötvös corrections.

Lamont scientists plan to continue to test the Graf sea gravimeter throughout the IGY, and they hope that it will eventually take its place aboard all oceanographic research vessels and become a standard method of gravity measurement.

A Report on the United States Program

The following is a brief account of some activities in the United States IGY program during the first five months of the Year, 1 July to 30 November, 1957. It is condensed from an article entitled "International Geophysical Year: A Report on the United States Program," by Hugh Odishaw, Executive Director of the US National Committee for the IGY, published in Science, *Vol. 127, No. 3290, pp. 115–128, January 17, 1958. Background material on the dimensions of the various programs in which early IGY findings are described here may be found in the first several issues of the Bulletin.*

Physics of the Upper Atmosphere

Solar Activity: On the eve of the IGY's beginning, the first major solar flare of the program, that of 28 June 1957, was observed at the Krasnaya Pakhra Observatory in the Soviet Union. A message was flashed to the World Warning Agency operated for the IGY by the National Bureau of Standards at Fort Belvoir, Virginia, which declared a state of Alert beginning at 1600 UT, 28 June. (Alerts are declared when there is probability of solar disturbances. When the probability is high that terrestrial disturbances will also occur, Special World Intervals are promulgated calling for increased measurements of solar-terrestrial phenomena.) The first such interval in IGY was broadcast on June 29, to commence at 0001 UT 30 June. Throughout the world observations of the sun were intensified, and balloons and instrumented rockets were sent up by many nations to observe the increased ultraviolet and X-radiation and to monitor cosmic ray intensity. Observations and measurements were speeded up to record more carefully and fully the northern and southern lights, to measure disturbances in the earth's magnetic field, and to probe the ionosphere.

It had long been thought, but not heretofore conclusively established, that absorption of radio signals during such periods of maximum solar activity must be caused by increased ionization in the lower atmosphere. On 4 July, radio signals received from a rocket fired up through the ionosphere demonstrated the presence of an additional layer of ionization extending for about 12 mi below the normal lowest point. Even more remarkably, the rocket data showed that the normal ion distribution throughout the ionosphere above the D, or lowest, layer, seemed to remain undisturbed during the blackout. In another recent IGY rocket experiment, it was ascertained that the additional electron layer was caused by solar X-ray emission associated with the occurrence of solar flares.

In another portion of the IGY program, at the Mount Wilson Observatory in California, measurements are being made of the magnetic field of the sun at its surface. It has already been found that magnetic fields at the sun's surface may be very high, as much as 8,000 times that of the earth's field at the equator. These magnetic fields are thought to play a very important role in disturbances and storms on the sun's surface as well as in sunspots.

It has been suggested, but not previously established, that the magnetic effects we observe on earth during magnetic storms may be due to great electric currents, of perhaps several hundred thousand amperes, flowing around the earth high in the atmosphere. Two of these currents are believed to circle the North and South magnetic poles while the third circles the earth at the geomagnetic equator.

Stations in South America and in the Pacific Ocean—at Guam and Koror in the Western Pacific, and at Jarvis, Palmyra, and Fanning Islands in the Eastern Pacific—were established especially to study the existence of the so-called "electro-jet." The electro-jet is believed to be the equatorial electric current, but narrowed down into a "neck" of limited horizontal dimensions with consequent increased current density and intensified activity at local noon. The US

Coast and Geodetic Survey, which operates many of the magnetic observatories established by the United States, reports tentative confirmation of this phenomenon. Initial data from Koror reveal the existence of the equatorial electro-jet and its rather limited horizontal extent.

Aurora and Airglow: The 39 stations and hundreds of amateurs participating in the United States program have already had much to observe. The fact that the IGY was scheduled for a period of expected maximum solar activity has greatly enhanced the value of the program, for already three of the largest solar flares (class 3+) have resulted in extensive auroral displays visible as far south as Havana, Cuba. Synoptic maps have been prepared depicting all auroras observed and reported from the United States during the months of July and August. This is the first time that such a complete description of auroral data has been assembled for the use of geophysicists studying auroral and such related phenomena as ionospheric and geomagnetic effects.

English scientists at the University of Manchester have reported that coordinated radar observations indicate that auroras occur simultaneously in the Northern and Southern Hemispheres, a condition long believed to be true by scientists, but not previously established. Additional polar radio data which provide further evidence on this question have been obtained in the United States program.

The systematic reduction of the variations in the intensity of the night airglow is proceeding. Charts of the "patchiness" and movement of night sky luminosity resulting from oxygen emissions are being produced on a routine basis from IGY observations.

Ionospheric Physics: New information about the farthest reaches of the atmosphere is being obtained from the study of "whistlers"—whistle-like sounds which can be detected at very low radio frequencies. These signals, originating in lightning flashes at the surface of the earth, swing out thousands of miles along the earth's lines of magnetic force before they return to earth in the opposite polar hemisphere. Early IGY experiments demonstrated that the ion density and molecular concentration along the whistler path at altitudes of as much as twice the earth's radius must be much greater than formerly anticipated. Indeed, there seems to be confirmation for the theory that the earth's atmosphere extends far beyond the level where it had been previously thought to "end" and that there may be a very tenuous atmosphere—the sun's corona—filling all the space between the earth and the sun.

Other records of previously unexplained radio noise at very low frequencies have stimulated the hypothesis that solar particles arriving in the very high atmosphere transfer energy to very low frequency radio waves there. According to this hypothesis, the radio signals thus amplified are the very low frequency radio emissions observed at ground level. Data now being gathered will throw further light on this hypothesis, which is based on the traveling wave tube principle as noted by Roger Gallet.

Ionospheric characteristics are deduced from the analysis of echoes arising from the reflection of radio pulses transmitted to the ionosphere at vertical incidence. Since the IGY began there have been several major solar events that caused disruption of long-range, short-wave radio communications which depend upon reflections from the ionosphere. For the first time, a synoptic picture has been obtained of the growth and decay, station by station, of such fadeouts.

The principal, regular variation in the ionosphere is the diurnal one. Ionization density increases during the day, when the sun is present, and decreases at night. What would happen to the ionosphere during long absences of solar radiation and the nature of any diurnal variation during such periods have been subjects of speculation. Only at or near the geographical poles can these questions be examined, and the South Pole affords the best platform for an observatory. Investigations during the last year at the

South Pole Station of the United States have yielded interesting results: in spite of the absence of the sun, the electron concentration seems to remain very high throughout the polar night; moreover, there is a diurnal variation that can only, it appears, be associated with geomagnetic activity. The evidence so far obtained suggests that ionospheric behavior in the two polar regions is essentially the same. Analysis of these observations may appreciably alter our concepts of the ionization and recombination processes in the atmosphere.

Cosmic Rays: These electrically-charged particles, which bombard the earth continuously and from every direction, are markedly influenced by the earth's magnetic field: low energy particles are deflected toward the vicinity of the two geomagnetic poles, and only the more energetic ones penetrate at the middle latitudes.

Investigations at the 20 United States cosmic ray stations have already provided interesting results. The work of scientists from the University of Chicago has shown that the location of the line where the cosmic ray intensity is a minimum—the "cosmic ray equator"—deviates systematically from the geomagnetic equator. The experiments leading to this result began in 1954–55 when a neutron pile detector was installed aboard the USS *Atka*, which conducted a reconnaissance of the Antarctic prior to the establishment of IGY stations in following years. Measurements were made on the trip down, around Antarctica, and back; these measurements were repeated in the 1955–56 and 1956–57 Antarctic seasons aboard the USS *Arneb* and were supplemented by aircraft flights in a zigzag pattern around the geographical equator in October 1956. These studies showed a 40° to 45° shift to the west of the inclined cosmic ray equator with respect to the magnetic equator. J. A. Simpson suggests that this warping may well indicate the presence of important magnetic fields, probably of extraterrestrial origin, which alter the trajectories of the incoming primary cosmic ray particles.

Typical of international cooperation in this program during the IGY is the Swedish-Canadian-American cosmic ray experiment carried out aboard the Swedish merchant ship M/S *Lommaren* sailing between Sweden and the Union of South Africa.

Preliminary balloon flights in and near Minnesota with ionization chambers have shown that, at constant altitude, there is a strong latitude effect. This is so strong that latitude changes as small as 7 mi can be detected by cosmic ray measurements. Other balloon experiments at Fort Churchill and Thule have shown that cosmic rays of lower energy (less than about 2 Bev) effectively disappeared during the present period of high solar activity, with ionization at high altitudes down to half the value it had in 1954 or 1955.

Perhaps one of the most interesting observations made in the course of IGY cosmic ray experiments was that of relatively soft radiation in the high atmosphere, associated with primary auroral radiations. Rocket and balloon flights have led to the positive identification of the soft radiation: it is X-radiation in the range between 10^4 and 10^5 electron volts. There appears to be good correlation between the presence of such radiation and solar, magnetic, and auroral activity. The effect is probably a secondary one; it is believed that incoming auroral particles create the X-rays by bombardment of atmospheric particles.

There were 29 rockets fired in the pre-IGY test period. These included Aerobees, Rockoons and Nike-Cajuns. Firings took place at the newly erected facilities at Fort Churchill (with Canadian cooperation) as well as at White Sands, New Mexico, Guam, and from shipboard off the California coast and in the North Atlantic. These firings were successful, and the preliminary information gained was of considerable value in the final detailed planning of the schedules for firings during the IGY period.

The United States IGY program in rocketry actually began on 5 July 1956 at Wallop's Island, Virginia, when the first IGY test rocket was fired successfully. To date, 83 rockets have been fired during the IGY. Included have been those in programs conducted at Fort Churchill (nine Aerobees, five Nike-Cajuns); White Sands (two Nike-Cajuns); Point Mugu, San Nicolas Island, California (13 Nike-Deacons); a shipborne operation in the Arctic (18 Rockoons) and a shipborne operation in Pacific and Antarctic waters, concluded in mid-November (36 Rockoons). The following are some preliminary findings:

1. A firing at Fort Churchill indicated that the first atmospheric temperature maximum occurred at an altitude of about 60 km. Normally, this maximum is found below 50 km at lower latitudes, indicating that, at northern latitudes, the rise is more gradual. (Temperatures decrease up to the stratosphere, rise during the next 20 to 30 km, decrease through the next 30 km, and then rise again.)

2. A rocket instrumented for ionospheric studies was sent through a polar radio blackout for the first time. Data were obtained which indicated that a very dense D-region exists at a significantly lower altitude and with a much greater density than is found at lower latitudes.

Another firing at Fort Churchill during the summer of 1957 measured electron distribution in the ionosphere up to an altitude of 250 km during a polar blackout. The results of this experiment confirmed theories that the D-region of the ionosphere is primarily responsible for radio blackouts.

3. During a series of firings with Aerobees and Nike-Cajuns instrumented for studies of pressure, temperature, and density, it was determined that the distribution of pressure and temperature in the atmosphere at high latitudes is much different than it is at lower latitudes. Many of these rockets attained altitudes greater than 200 km, and thus the first density measurements made at high latitudes were recorded. Launchings were made during both summer and winter, day and night. The resulting data indicate that the density of the high atmosphere is under strong solar control. There appear to be a latitude effect, a seasonal effect, and a strong diurnal effect; none of these effects appears at lower altitudes at Fort Churchill or lower latitudes.

4. An experiment with a mass spectrometer at Fort Churchill appears to confirm the belief that diffusive separation of gases under gravity is present above 100 km at that latitude. Below this point the gases in the atmosphere appear to be well mixed.

5. During July and August 1957 the DAN rocket flare patrol program took place at Point Mugu, California. This program was primarily directed toward determining the radiation source of the fadeouts resulting from flares observed on the disc of the sun. For the first time, measurements were made of X-ray and ultraviolet bursts from the sun during a solar flare. These data will help in explaining radio blackouts, which are present during periods of unusually high degree of ionization and which are closely associated with solar flares.

6. During the shipboard firings in the Arctic, an excellent survey was made for the first time of auroral particles and their association with actual auroras. Also conducted for the first time at high latitudes were magnetic field measurements.

Satellites represent an extension of rocketry useful in probing the high atmosphere. The USSR launched its first satellite on 4 October 1957. This satellite, a sphere nearly 23 inches in diameter and weighing about 184 pounds, carried transmitters broadcasting on frequencies of 20 and 40 mc/sec. The second Soviet satellite was launched on 3 November. Weighing about 1120 pounds, the last rocket stage was reported to carry two transmitters (20 and 40 mc), a dog, and instruments to measure satellite temperatures, ultraviolet light, X-rays, and cosmic rays. The initial period of the second satellite's revolution was 103.7 min with an apogee of approximately 1056 mi and perigee of about 150 mi.

The United States program is proceeding

according to schedule. The Navy has responsibility for the rocket system and launching in the Vanguard series, the Army for the Jupiter-C series. The IGY Committee of the Academy is responsible for the scientific aspects, both internal experiments and the radio and optical observation programs. Two types of satellites have been designed: test spheres for use during the test period for the Vanguard rocket system and equipment-laden satellites thereafter for both the Vanguard and Jupiter-C vehicles.

Earth's Heat and Water Regimen

Meteorology: For the first time, synoptic meteorological charts of the vast unknown continent of Antarctica are being drawn on a daily basis at the Antarctic Weather Central, operated at Little America with the aid of scientists from a number of nations. As a result, weather forecasting has already been markedly improved in the Southern Hemisphere. Aside from the forecasting and synoptic aspect, the scientific value of the observations in Antarctica are potentially of great value in understanding atmospheric circulation and its relation to solar radiation and topography.

The Antarctic is the coldest place on earth. The continent itself is elevated and mountainous, the South Pole being almost 10,000 ft above sea level. Last September 17, the South Pole Station reported the lowest temperature yet recorded, 102.1° below zero.

In the Antarctic meteorology program, large neoprene balloons have been sent to altitudes of over 80,000 ft, and the average is about 60,000 ft. Meteorological balloons sent up at 112 non-Antarctic United States stations are reaching altitudes ranging from 85,000 to 107,000 ft.

In addition to these broad-scale programs, several specialized programs are underway, and preliminary results have been received. For example, there is in Little America an instrument which measures the minute quantity of ozone in the air at the ground level. Ozone mainly occurs in a layer-like region about 15 mi high in the earth's atmosphere. Some ozone diffuses to the ground or is formed at lower levels by ultraviolet light. It has been noticed that, at Little America, there is about 25 per cent more ozone at the ground than there is in New Mexico. Although ozone is a minor constituent of the atmosphere, it is thought to play an important role in the circulation of the high atmosphere, because of the energy it can absorb and release.

Another minor constituent of the atmosphere which may play a major role in climatic changes is carbon dioxide. Our industrial civilization burns tremendous quantities of fossil fuel each year, pouring millions of tons of carbon dioxide into the atmosphere. Most of this is absorbed by plant life and by the waters of the oceans, but there is the possibility that eventually the carbon dioxide content of the atmosphere will rise enough to affect the world's climate. It has been found already that the concentration of carbon dioxide in the Antarctic is about the same as in non-industrial areas over the rest of the world.

Glaciology: Technical advances and discoveries have already been made in the two greatest reservoirs of ice in the world, Greenland and Antarctica. In Greenland, scientists and engineers of the US Army's Snow, Ice and Permafrost Research Establishment have perfected techniques for drilling deep holes in the ice with hollow drills, much as an oil well is drilled, to obtain a "core" of ice. The first hole was drilled in Greenland in 1956 and reached a depth of over 1000 ft. The second hole was successfully drilled in 1957 in Greenland, and a similar operation is now under way in the Antarctic in Marie Byrd Land.

The recent boring in the ice of Greenland reached a depth of 1438 ft. A complete series of cores 4 inches in diameter was obtained from the first 1040 ft. Below this depth, recovery of the core is difficult because the release of strains as the ice is drilled causes the ice to shatter. Dissolved gas, which is under great pressure in the ice at these depths, also causes trouble because it bursts through pockets in the ice, increasing the amount of shattering. However, a core was obtained from 1200 to 1220 ft, and another from 1320 to 1338 ft. These cores are being studied with great care in the laboratory, for they are an invaluable index of climate and precipitation over the past many hundreds of years. Their layers are studied in much the same fashion as tree rings. From the first hole in Greenland, the 1912 layer was identified by the ash from a volcano which erupted in Alaska. The dust from the great explosion in 1883 of the volcano Krakatoa, in the East Indies, will be a help in checking the dating of the annual layers of precipitation in the cores. Because precipitation is lower in the Antarctic than in Greenland, it is expected that this ash layer will be found at a depth of about 150 ft in Greenland and at about 60 ft in the Antarctic.

The great ice sheet of the Antarctic, over 6 million square miles in extent, cannot be studied in anything but a spotty fashion. However, teams of glaciologists, seismologists, and support personnel are traveling by tractors and special over-snow vehicles thousands of miles across the ice in a series of traverses to obtain the profile of ice thickness across the continent and to attempt to learn something of the underlying terrain, or formation of the ice-covered earth. For example, after the Byrd Station was established some 600 mi from Little America by a tractor party, a traverse team then crossed the ice shelf from Little America and continued to Byrd Station, exploring the ice as it went. During this first traverse, it was discovered that Byrd Station, at an elevation of about 5000 ft above sea level, stands upon ice almost 10,000 ft thick. Further explorations will reveal whether this is a frozen fjord or inland sea and what part of this submergence may be due to the bending inward of the earth's crust as a result of the weight of the ice.

United States scientists at two locations in the Arctic basin are now making studies of the melting of the ice pack, the freezing of new ice, and the general relations between the state of the ice and the local climate.

Drifting Station A is now located in the region of latitude 85.30°N and longitude 170°W, 310.5 miles from the Pole. It is on the ice pack itself, on a floe a few miles in area and only some 7 to 12 ft thick. Scientists there have noted that during the past summer season about 12 inches of ice on the upper surface have melted, while as much as 18 to 24 inches of new ice have frozen on the bottom of the floe. This observation will be placed in proper perspective when all the information on radiation from the sun, ocean currents, and temperatures of the air, ice, and oceans has been studied.

Recently, in a test of instrumentation developed by J. C. Swallow of the National Institute of Oceanography in England, the *Atlantis*, a research vessel of the Woods Hole Oceanographic Institution, and the British research vessel, *Discovery II*, explored the eastern edge of the Gulf Stream and for the first time were able to map the underlying flow of water. They found that, at depths of about 6500 ft, there was either very little or erratic movement; shallower depths showed set to the northeast, as expected, but at about depths of about 9000 ft, the current sets in the opposite direction—southwest—at the relatively high speed of 8 mi per day. The Swallow neutral buoyancy float was tracked electronically in this work, providing a new technique which enables IGY oceanographers the world over to map both surface and relatively deep currents.

Several United States ships have already made extensive cruises for the IGY. The work of the *Atlantis* has already been mentioned. The *Crawford*, also of the Woods Hole Oceanographic Institution, made a four months' cruise in the *Atlantic*. The *Crawford* reoccupied many stations taken years ago by the German ship *Meteor* and discovered that there have been pronounced changes in the amount of oxygen dissolved in the Atlantic in the region of 15° South latitude. The difference in oxygen content over the past 30 years may mean that deep bottom water is not being formed as fast now as it was previously, but further data and analysis are needed for proper interpretation of the present observations.

The *Vema*, a research vessel operated by the Lamont Geological Observatory of Columbia University, has completed an extensive cruise in the Southern Atlantic Ocean, working along the coasts of South America and Africa, and crossing the Atlantic at high southern latitudes between Argentina and Capetown. The *Vema* cooperated with the *Bahia Blanca*, a survey vessel of Argentina, in making explorations of the submarine crust by seismic methods. Considerable marine biological work was also done, and Lamont has reported that living organisms—a small shellfish and a worm one-fourth of an inch long—were recovered alive from depths of 13,200 and 16,200 ft respectively. Lamont scientists believe these to be record depths for retrieval of live marine samples. (The *Vema* has since left New York on a second cruise.)

In the Pacific, the *Brown Bear* of the University of Washington worked in the Northeast Pacific Ocean last summer. The deep currents in that area were studied. The *Horizon* and *Baird*, research vessels operated by the Scripps Institution of Oceanography of the University of California, left San Diego in October for a two-ship, five-month expedition through the Central and Southeast Pacific. They will make seismic explorations of the submarine crust, study surface and deep currents, take bottom samples and occupy about 40 oceanographic stations, where water samples down to great depths will be obtained for later analysis of chemical content. The *Jakkula*, of the Agricultural and Mechanical College of Texas, will cruise in the Caribbean Sea and western Atlantic in the summer of 1958.

Another part of the IGY oceanography program is the study of the mean sea level over the period of the IGY. It has been found from study of tide data that there seems to be an exchange of water between the Northern and Southern Hemispheres as the seasons change. New tide gauges are being set up to supplement the existing network: instruments are already operating in Bermuda, Iceland, and the Azores in the Atlantic, and in the Caroline, Marshall, and, with the cooperation of French scientists, at French islands in the Southeast Pacific. A station is in operation on Pitcairn Island under the supervision of a descendant of one of the mutineers of HMS *Bounty*.

Geophysicists on Drifting Station A, in the Arctic Ocean, reported on August 12, 1957, that the ice floe on which their station is established had floated over an underwater mountain range, or ridge, rising more than 5,000 ft above the ocean floor. The ridge was discovered in the course of routine seismic depth soundings and gravimetric measurements when the station was at 82° 54′ N, 167° 28′ W—about 850 mi northwest of Barrow, Alaska, and about 550 mi from the North Pole—drifting generally toward the Pole. The soundings indicated a rapid decrease in ocean depths, from more than 10,000 ft to slightly less than 5,000 ft. Increased gravity values indicated a corresponding substantial compensation in the crustal mass. On November 23, 1957, the station recrossed the ridge and was able to confirm its original report. Scientists of the Soviet Union are doing similar work on two stations in the Arctic Basin.

In the Antarctic the ships of the various nations supporting scientific stations on the continent engage in oceanographic observations enroute to and from the area. Thus, USSR and New Zealand ships have added to our knowledge of these waters. Ships of the US Navy Task Force 43 are also exploring the coast, charting the bottom, and taking bottom and water samples for future study.

Earth's Structure and Interior

Seismology: Several new types of seismographs with wide range and high sensitivity have been located at observatories throughout the world. The Lamont Geological Observatory has constructed ten special long period seismographs and has installed most of them at observatories ranging from Hawaii to Fiji and from Bermuda to the Antarctic. These long-period instruments are sensitive to surface waves of periods of about 400 sec, generated only by the very largest earthquakes. These wave-lengths are so long that they penetrate to the interior of the earth, and in fact, the whole earth itself may be set into vibration. Recently, workers at Lamont have discovered the existence of certain intermediate waves with periods of about 100 sec. These waves, which were previously only known in the crust in continental structures, have been identified now in the mantle, or the next layer beneath the crust. These waves permit better resolution of structural details than the longer 400-sec waves, and study of their propagation is expected to provide new information on the distribution of materials in the interior of the earth.

Seismologists from the Department of Terrestrial Magnetism of the Carnegie Institution of Washington worked on exploration of the roots of the Andes Mountains in South America last summer and fall. They have found roots of unsuspected depths and are now working on their data to obtain better understanding of the crustal structure under this great mountain chain.

Seismologists of the US Coast and Geodetic Survey have installed new seismic equipment in the Pacific at Truk and Koror and have been obtaining records of Pacific earthquakes. These new stations, together with those in the Antarctic, will add significantly to our knowledge of seismicity and the structure of the earth.

The first successful measurements of gravity on the open sea were made on November 22, 1957, by J. Lamar Worzel of the Lamont Geological Observatory, using a sea gravimeter developed by Anton Graf of Munich. In the past, gravity measurements for oceanic areas required measurements aboard submarines at quiet depths below the surface. The difficulty of obtaining and fitting submarines for this purpose made it impossible adequately to survey the seas: only about 5,000 such measurements have been made throughout the world. The new instrument, mounted on a gyro-stabilized platform, will make it possible to obtain data simply and quickly anywhere at sea with a precision of one part per million, similar to that attainable on land.

IGY data

The preceding sections suggest the nature of the IGY activities as shown by the US IGY effort in the first few months of the program. With 67 nations cooperating in the endeavor and some 10,000 scientists and technicians making observations and measurements at more than 2,000 stations, the volume of data stemming from the program will be considerable. To ensure the safety of the raw data and their accessibility, the international IGY committee has approved the establishment of three world data centers—in the US, in Europe, and in the USSR.

Each data center will acquire a complete set of all IGY data. Each center will archive and index its compilation of data, holding it accessible to research workers. Schedules for the orderly flow of data into the centers have been arranged. These schedules vary, depending upon the nature of the data in a given discipline and upon the definition of a reasonable "lot" of data to simplify the handling problems. A "lot" of data may be one month's observations in one field or several months' in another.

The procedures for handling data and forwarding them appropriately involve a series of steps of the following kind: (i) collection of a "lot" of data at a field station, (ii) transmittal of the "lot" to the home laboratory of the field station, (iii) checking of field data at the home laboratory, (iv) transmittal to one of the World Data Centers, (v) copying of the data by one World

Data Center for the other two and appropriate transmittal, and (vi) indexing and archiving at World Data Centers.

The data centers are in operation, and data are flowing into the centers. The steps outlined above lead to a peak early in 1958, a steady 18-month plateau through at least the first six months of 1959, followed by a "clean-up" period extending probably into the first quarter or so of 1960.

Acknowledgment: The preparation of this narrative would not have been possible without the cooperation of many scientists and institutions engaged in the IGY program. Although some of them are mentioned in the text, it has not been possible in this summary to refer to all. The United States IGY program has only been possible because so many individual scientists as well as public and private institutions have participated and cooperated in the endeavor. Particular acknowledgment is made to members of the Academy's IGY staff who have helped in the preparation of this report: Stanley Ruttenberg, Phillip Mange, John Hanessian, Jr., and John Truesdale.

Satellite Telemetry

This article is based upon material furnished by Whitney Matthews of the Naval Research Laboratory and George H. Ludwig of the State University of Iowa.

In order that non-recoverable satellites may be used for direct observations in space, they must be equipped with telemetering systems—systems designed to record observations made by the satellite's instruments, to encode those observations for transmittal to ground stations and then to accomplish the actual transmission. Without such systems, only ground-based satellite experiments could be conducted. With them, instruments may be used to make observations directly in space, unhampered by an intervening atmosphere.

Special Requirements

Requirements for a telemetering system to be used in an earth satellite are much the same as for any such system, but qualities normally considered desirable become essential in satellite telemetry. The cost of putting a satellite into orbit, the longer period available for telemetry, and the impossibility of maintenance all place unusual emphasis upon reliability. The high cost in vehicle power and weight required to place each additional ounce in orbit makes it necessary to keep telemetering weight factors extremely low. To keep the system operating as long as possible on self-contained batteries, power needs must be held to the minimum.

A new and major problem in the design of satellite telemetry systems is that of providing memory devices. Since US satellites will pass over nearly two-thirds of the earth's surface, it is impractical to establish ground stations in sufficient numbers to assure continuous monitoring and recording of satellite transmissions. With ground stations limited to reasonable numbers, the probability of obtaining significant data at the particular times when satellite signals can be monitored is not high enough—particularly in view of the nature of many of the phenomena to be studied. Therefore, memory devices are needed to store information collected during an orbit and to release data on receiving an appropriate signal from a ground station.

Each of the earth satellites to be launched by the United States during the International Geophysical Year will contain a different combination of scientific experiments. One group of satellites will telemeter data continuously, as it is observed. A second group, either using satellite-borne tape recorders for storing synoptic data or requiring relatively high-power consumption for making measurements, will carry "command" receivers to provide data transmission upon interrogation by ground stations.

With one exception all telemetered data from US-IGY satellites will be transmitted by amplitude modulations (AM) of the signals from the radio transmitter operating at 108 mc.

Lyman-alpha Package

Instruments carried in satellites of one design will measure ultraviolet radiation in the Lyman-alpha region of the solar spectrum, satellite temperature, and the impact upon the satellite of micro-meteoric particles. The instrumentation has been developed by the Naval Research Laboratory.

Solar radiation always contains energy i the Lyman-alpha region, with marked increases occurring during periods of sola flares. The Lyman-alpha satellite experiment will study both the Lyman-alph radiation from the quiescent sun and th peak values associated with solar flares. Solar Lyman-alpha radiation will be measured by an ionization chamber sensitiv only in the desired region of the solar spectrum.

CALIBRATION & IDENTIFICATION

Fig. 5. *Block Diagram of Telemetry System for the First US-IGY Artificial Earth Satellite.*

In order to interpret the data recorded by the ionization chamber, the aspect, or orientation, of the satellite with respect to the sun must be known. Aspect information will be supplied by signals from silicon solar aspect cells located in the equator of the satellite.

Both internal and external satellite temperatures will be measured by means of thermistors located inside the instrument package and on the outer shell near one pole and at the equator.

The remainder of the experiments in satellites of this type are concerned with collisions between the satellite and micrometeoric particles. Three, and possibly four, types of measurements will be made. The first type will use small erosion gauges, consisting of thin film resistors coating a glass attached to the outer surface of the satellite. By monitoring the resistance of these gauges it will be possible to detect wearing away of the resistive elements by minute particles colliding with the satellite. A cadmium sulfide detector, consisting of a photo-resistive element covered by an opaque material, may be substituted for one of these erosion gauges. In sunlight, the resistance of this element will be a function of the amount of opaque material removed from the sensitive element by collision with these microscopic particles.

The third micrometeor experiment uses a group of sensitive microphones as detecting elements. Signals from these microphones, which are attached to the skin of the satellite, will drive counting circuits associated with the telemetry system; this in turn, will transmit data continuously, providing the cumulative number of collisions.

In addition to the telemetry channels required for transmitting the above data, other channels will be used to monitor battery voltages and provide calibration and identification.

Fig. 5 shows the flow of information from the detecting elements through the telemetry system and transmitter.

Signal Codes: The telemetry encoder system for the Lyman-alpha package transmits a continuous series of high-frequency audio bursts. A complete set of all input signals, called a "frame" or "scan," contains 16 bursts and 16 spaces between bursts. Intelligence is carried in (1) the burst frequency, (2) the duration of the burst, and (3) the duration of the interval

Table I. *Telemetry Channel Assignments: Lyman-Alpha Environmental Satellite*

Burst No.	High Frequency Burst		Burst Duration		Interval Between Bursts	
	Channel	Function	Channel	Function	Channel	Function
1	A	Instantaneous Lyman-α	A1	Polar erosion A	A2	Battery volts
2	B	Solar aspect	B1	Differential pressure	B2	Short calibrate
3	A	Instantaneous Lyman-α	A1	Polar erosion A	A2	Battery volts
4	B	Solar aspect	B1	Differential pressure	B2	Short calibrate
5	A	Instantaneous Lyman-α	A1	Polar erosion A	A2	Battery volts
6	B	Solar aspect	B1	Differential pressure	B2	Short calibrate
7	C	Meteor count, units	C1	Long calibrate	C2	Battery volts
8	D	Meteor count, tens	D1	Package temperature	D2	Polar skin temperature
9	A	Instantaneous Lyman-α	A1	Polar erosion A	A2	Battery volts
10	B	Solar aspect	B1	Differential pressure	B2	Short calibrate
11	A	Instantaneous Lyman-α	A1	Polar erosion A	A2	Battery volts
12	B	Solar aspect	B1	Differential pressure	B2	Short calibrate
13	A	Instantaneous Lyman-α	A1	Polar erosion A	A2	Battery volts
14	B	Solar aspect	B1	Differential pressure	B2	Short calibrate
15	E	Meteor count, hundreds	E1	Polar erosion B	E2	Equator skin temperature
16	F	Peak Lyman-α	F1	Equator erosion	F2	Cadmium sulfide cell

between bursts. Thus, 48 potential information channels are provided, even though only 17 different data signals will be transmitted. Burst frequencies lie between 5 and 12.5 kc. Burst durations and blank intervals can vary from 4 to 30 milliseconds, although the dynamic ranges of many intervals are restricted to permit additional telemetry time for the solar Lyman-alpha experiment.

The telemetry channel assignments currently planned are shown in Table I. Transmission on Channels A and B, presenting solar Lyman-alpha and solar aspect signals are repeated several times during a scan. This frequent repetition—together with high-frequencies which permit continuously-variable signals to follow instantaneous changes—provides the necessary information from the input devices. Technical considerations dictate a similar repetition on the associated time interval channels A1, A2, B1, and B2.

The general character of a set of calibration curves for a typical telemetry encoder is shown in Fig. 6.

Cosmic-Ray Package

The satellite carrying the cosmic-ray experiment developed by the State University of Iowa will be launched by a vehicle developed by the US Army.

The radio transmission and telemetering system for the cosmic-ray satellite is being produced and assembled at the Jet Propulsion Laboratory of the California Institute of Technology.

At present, two different sets of instruments or "payloads" are being prepared. One set measures cosmic rays, meteoric density, and satellite temperatures. The other payload provides for these same measurements but adds a tape recorder, which will be geared to a ground interrogation system. The particular payload in use will be announced when the satellite is launched.

Cosmic-ray experiments: The measurement of cosmic-ray intensity outside the atmosphere of the earth and over a wide range of latitudes will provide new knowledge about these particles and about the earth's geomagnetic field. A single satellite-borne Geiger counter has been designed to measure the total cosmic-ray intensity without respect to direction. The instrument includes a storage system, which accumulates a record of the average counting rate for short periods of time. The time required for one orbit can be split into any number of segments and the average intensity for each segment can be assigned with a statistical uncertainty depending on the number of segments—the greater the number of segments the less the uncertainty.

The data to be obtained from such a system are useful for the (a) determination of the effective geomagnetic field; (b) study of time variations of primary radiation intensity, including their correlation with solar and magnetic observations and with the intensity of secondaries observed at ground stations; and (c) provide for the first time a comprehensive geographical survey of primary radiation.

Measurements of density of meteoric matter: Impact microphones (as used in the Lyman-alpha satellite) and erosion gauges, will be carried in the cosmic-ray satellite for measurements of the density of minute meteoric particles. Some of the erosion gauges are grid-like structures electrically connected in parallel. When one of the grid wires is hit by a particle physically large enough to break the wire, the over-all resistance of the string changes in a step-wise manner. Also included in the set of gauges is one composed of a very thin film of resistive material. The total resistance of this gauge will change slowly as the material is removed by the "sandblasting" action of cosmic dust, which travels at a very high velocity relative to that of the satellite. The gauges for density measurement of meteoric material were developed and provided by the Air Force Cambridge Research Center.

Telemetry equipment: Each of the payloads described above for cosmic-ray satel-

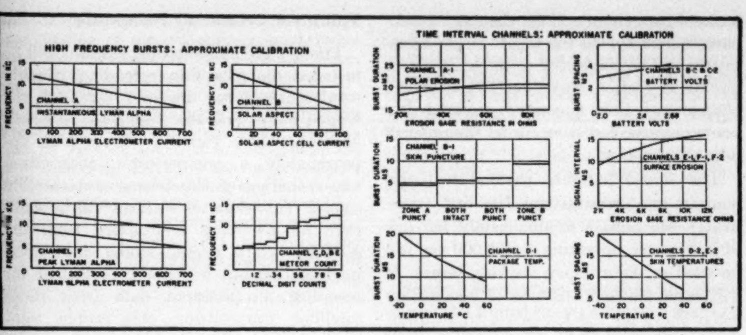

Fig. 6. *Representative Calibration Curves for a Typical Lyman-α Satellite Telemetry Encoder.*

lites will contain two transmitters; one will operate on the primary tracking frequency of 108.000 mc, and the other on 108.030 mc. Each of the two transmitters in the first payload will operate continuously and over four simultaneously used channels. One transmitter, of the Minitrack type, using a turnstile antenna, will radiate approximately 60 mw of power on 108.030 mc. It will operate from a battery supply which should enable it to transmit for approximately two weeks. The telemetering will be by AM over standard RDB telemetering Channels 2 through 5 (518 to 1320 cps).

The other transmitter will radiate approximately 10 mw of power on 108.000 mc. Its battery supply should enable it to operate for approximately two months. This transmitter will also carry information over four channels on the same RDB telemetering frequencies—in the form, however, of small-deviation phase modulation. The antenna for this transmitter will be formed by electrically splitting the satellite payload shell and driving the two pieces, thus generating a linearly polarized signal.

Although eight different telemetering channels will be available, two of these will be used in duplicate; therefore, only seven types of information will be carried. The higher-power transmitter will carry two temperature measurements: channel 2 (518–602 cps) will carry a measurement of the temperature of the outside of the payload case somewhere near the pole, and channel 3 (675–785 cps) will carry a measurement of the temperature of the interior of the transmitter. Channel 4 (888–1032 cps) will carry information derived from an impact microphone measuring the frequency of collision with micrometeors. Channel 5 (1202–1398 cps) will carry cosmic-ray information, and is of the most interest so far as telemetry reception from other parts of the world is concerned.

Channel 5 will carry information concerning measurement of the instantaneous ionization caused by cosmic radiation. The instrumentation consists of a Geiger-counter tube operating into a scale-of-32 circuit (a circuit in which 32 input signals generate one output signal). The output of the last scaler circuit controls the frequency of the telemetering subcarrier oscillator. The tone of the oscillator will change each time a new count goes into the last circuit of the scaler. The tone will shift back and forth every time 16 total counts have been received. This is expected to happen on the order of once per second.

The information from the impact microphone will be carried in a similar manner, the output of the microphone going into a scale-of-two circuit. The channel 4 subcarrier oscillator on the higher-power transmitter will be connected to the scale-of-two circuit in such a way that the tone will change each time a count is received. Impacts are expected to occur on the order of once every few seconds.

The second satellite payload will also contain two transmitters. The first transmitter will radiate approximately ten mw of power, and, operating on 108.000 mc, will be used as the primary tracking source. It will carry the four channels of information listed above for the low-power transmitter. This payload will also include a radio receiver for interrogations from primary IGY ground stations. The cosmic-ray instrumentation in the package includes a magnetic tape recorder for the purpose of recording cosmic-ray information during each orbit. Upon interrogation from the ground, the second transmitter will switch on; the tape-recorded information will be sent over this transmitter. The higher-power transmitter will again operate on 108.030 mc with a radiated power of approximately 60 mw. As in the case of the first payload, the low-power transmitter will send through a linearly polarized antenna, the high-power one through a turnstile.

Volunteer Telemetry Recording

Primary ground recording stations will be installed along a line extending roughly north-south down the east coast of the United States and the west coast of South America. These stations will provide approximately a one-per-orbit observation and recording of the telemetered satellite signals. This chain of stations will be sufficient for recording information from the satellites which release stored data upon interrogation but will not be sufficient for recording all pertinent data from those satellites transmitting observations continuously.

With the cooperation of British National Committee for the IGY and of local groups who will operate the equipment, two special telemetry receiving stations have been established in strategic positions near the geomagnetic equator at Ibadan, Nigeria, and at Singapore.

The US National Committee for the IGY solicits the assistance of all persons and organizations equipped to make tape recordings of satellite signals. Instructions on recording techniques and procedures for forwarding the tapes to the cognizant organizations are covered in the January 1958 issue of QST, the journal of the American Radio Relay League.

IGY Satellite Program Notes

The following report is reproduced from Science, *Vol. 126, p. 1334, Dec. 27, 1957.*

Soviet Satellite Carrier Rocket

On 8 December 1957 the president and the chief scientific secretary of the U.S.S.R. Academy of Sciences addressed a cable to the president of the U.S. National Academy of Sciences regarding the rocket carrier body of the first artificial earth satellite, which was launched on 4 October 1957. A similar cable was addressed on 9 December to Joseph Kaplan, chairman of the U.S. National Committee for the International Geophysical Year, by Academician I. P. Bardin, president of the Soviet IGY Committee. Because the substance of these two cables is identical, only the first is quoted:

DETLEV BRONK, *President*
National Academy of Sciences

According to available data some not entirely burnt remnants of the first earth satellite rocket have been scattered along a line including Alaska

and the west coast of North America. A thorough investigation of the not entirely burnt rocket remnants and the knowledge of the exact places of their fall are of great scientific significance as they provide valuable data concerning phenomena occurring when satellites enter the denser atmospheric layers. The USSR Academy of Sciences asks all the USA scientists to communicate the data concerning the fall of the rocket remnants and to send the remnants which were found to the Academy of Sciences Moscow USSR.

President of USSR Academy of Sciences
ACADEMICIAN A. N. NESMEYANOV
Chief Scientific Secretary of USSR Academy of Sciences
ACADEMICIAN TOPCHIEV

Although no evidence had come to light indicating that the rocket body of the first satellite had fallen in North America, a review of all available data and reports was initiated on 6 December when press dispatches from Moscow indicated that the U.S.S.R. believed the carrier body may have fallen on this continent. The results of this review, as of 11 December, were negative, and, on the same day, the president of the National Academy of Sciences accordingly addressed the following reply to the U.S.S.R. Academy:

PRESIDENT A. N. NESMEYANOV
Academy of Sciences of U.S.S.R.
Moscow

Reference your message and message Bardin to Kaplan our review thus far of sightings and trackings of satellite and investigation of reports of objects sighted do not indicate rocket or remnants fell in United States or its territories. We have no reports of finding of any such bodies. Your request being transmitted to trackers and others. It will be helpful if you can provide data you mention as available to guide our further search.

DETLEV W. BRONK, ***President***
National Academy of Sciences U.S.A.

Several observation programs are under way in the United States as part of the IGY effort in the tracking of all satellites. Photographic and visual tracking responsibilities have been assigned to the Smithsonian Astrophysical Observatory, 60 Garden St., Cambridge 38, Mass. Radio tracking responsibilities have been assigned to the Naval Research Laboratory, Washington 25, D.C. Reliable information on satellite sightings would be welcome. Photographic and visual data should be addressed to the Smithsonian Astrophysical Observatory and, similarly, radio data to the Naval Research Laboratory.

USNC-IGY

Thule Neutron Monitor Station

This report is based on material provided by Martin A. Pomerantz of Bartol Research Foundation. The Thule monitor was constructed by the Foundation and is operated by the U.S. Army Signal Corps.

The neutron monitor installation in Thule, Greenland (76.5°N, 68.8°W) was completed and put into operation on 27 August, completing an Arctic chain of three neutron monitor stations. Observations made at Thule are particularly significant because this station, at geomagnetic latitude 88°N, is closer to the geomagnetic pole than any other neutron monitor installation.

Because of the deflecting effect of the earth's magnetic field, more cosmic rays reach the surface of the earth in high geomagnetic latitudes than in lower latitudes. Only high-energy atomic particles can reach the earth at the geomagnetic equator but the velocity requirement is reduced as the poles are approached.

Most of the cosmic rays that reach sea level are mesons—the so-called hard component. These particles are unstable and disintegrate a short time after they have been produced in interactions between the relatively high-energy primary cosmic rays and the atmosphere at very high altitudes. Their intensity near sea level depends in a very complicated manner on continually changing meteorological conditions throughout the atmosphere up to the point of origin.

In contrast, the nucleonic components, although comprising only a small fraction of these secondaries that reach the earth's surface, consist of protons and neutrons produced in the atmosphere by incoming low-energy cosmic rays and do not display the meson dependence upon meteorological conditions. Hence, by confining attention to the nucleons much information can be obtained about the geographic distribution of cosmic rays and of the earth's magnetic field.

A neutron monitor of the type installed at Thule detects the secondaries of the relatively low-energy cosmic rays, upon which the effects of magnetic conditions in the vicinity of the earth are most pronounced. A decrease in cosmic-ray intensity, as a consequence of either deflection or deceleration of these particles, is often associated with magnetic storms. Rapid increases in the cosmic-ray intensity sometimes occur simultaneously with eruptions on the solar disk. These often coincide with ionospheric disturbances causing radio blackouts.

The basic arrangement for measuring the intensity of the nucleonic component comprises a structure, called a "pile," in which several neutron detectors (boron trifluoride proportional counters containing BF_3 gas enriched with B^{10}) are embedded. The pile itself, consisting of lead and paraffin, contains a material of high atomic weight (lead) in which incoming nucleons can interact; a number of neutrons are produced in each of the resulting explosions. A neutron moderator (paraffin) slows these disintegration products down and retains them until ultimately they pass through one of the proportional counters that serve as neutron detectors. In some respects, this structure resembles an atomic reactor, except that in this case, the nuclear fuel is the nucleonic component of cosmic rays.

Each of the counters embedded in the pile actuates completely independent electronic circuits, so that the failure of any single component is easily recognizable. The scaled counts are tallied by a printing numerical register, as well as by an operation recorder pen which enters a pip on a continuously-moving chart driven by each counter. A chronometer with electrical contacts causes the reading on the register, and the corresponding time, to be printed on tape every 15 minutes. The impulses from the counters are also combined and introduced into a counting-rate computer, which indicates the average number of counts per minute. This is recorded on a chart continuously moving at a speed of six inches per hour. This makes it possible to correlate the time-variation of any unusual changes in the cosmic-ray intensity with other geophysical or solar disturbances.

A detailed comparison of time variations and distinctive events occurring near the geomagnetic pole, but at widely different longitudes, is being carried out with two other stations located at Resolute Bay, (74.7°N, 94.9°W) and at Murchison Bay, Spitzbergen (80.0°N, 19.0°E). These are under the direction of D. C. Rose, National Research Council of Canada, Ottawa, and A. E. Sandström, Fysiska Institutionen, Upsala, Sweden, respectively.

The Establishment of a Calibration Standard for Gravimeters in Eastern Canada and the United States

M. J. S. Innes

Abstract—A program of gravimeter measurements for the establishment of a suitable gravity standard in eastern Canada and United States is described. It is shown that the consistency of nine independent measurements of the gravity differences between stations forming a north-south line from Ottawa to Washington is highly satisfactory and that this line is suitable for calibration purposes. The gravity differences depend fundamentally upon a gravimeter calibration made against values of gravity at Cambridge pendulum stations in Canada.

The combined gravimeter results lead to a value of -501.44 ± 0.25 mgal for the difference in gravity between the Dominion Observatory, Ottawa, and building of the Department of Commerce in Washington. Although this determination agrees within the limits of error with recent Gulf pendulum results, it is concluded that more pendulum work is required before an absolute basis for this calibration line may be adopted.

Introduction—Considerable progress in the development of a satisfactory gravity standard for North America has already been achieved. In 1952 and 1953 the Dominion Observatory employed pendulum apparatus on loan from Cambridge University to establish gravity at eighteen points over a wide latitude range between Mexico City and Fairbanks, Alaska [*Garland*, 1953, 1955]. These measurements, which involve a change in gravity exceeding 4000 milligals, have been repeated, for the most part at identical sites, by United States scientists [*Rose* and *Woollard*, 1955] using quartz pendulums of the Gulf Oil Company. Comparison of the two sets of data [*Innes*, 1957; *Gilbert*, 1957] reveals systematic discrepancies which are believed to reflect errors in estimating sub-base values to which yearly sets of measurements were referred. While these differences have yet to be resolved, the Mexico-Alaska line of pendulum values is expected to provide an accurate gravity standard for the North American continent and to make an important contribution toward the establishment of a homogeneous world gravimetric network as recommended by the International Gravimetric Commission in Paris [*Coron*, 1954].

The difficult accessibility of this line in Canada, however, limits its usefulness as a direct standard for the calibration of gravimeters, particularly those instruments having a limited range. Portions of the line have been useful in providing suitable control for local surveys, but generally distances to it, and between successive pendulum stations, are too great to carry out gravimeter calibrations as frequently and regularly as might be needed. Experience has shown [*Innes* and *Thompson*, 1953] that the calibration factors of gravimeters, particularly those of the North American type, are subject to considerable change with time. Recent investigation indicates that such changes sometimes occur over periods of short duration and are usually related to overheating of the instrument following the failure of a thermostat relay. To ensure consistent results in regional gravimeter work, calibration checks must therefore be carried out periodically, the requirements being at least two calibrations per year, preferably one just prior to the field survey and the other immediately after its completion.

A series of stations extending along a north-south highway passing through Ottawa, from Prescott, Ontario, to Maniwaki, Quebec, and having an overall range of 124 milligals [*Saxov*, 1956] has served for a number of years as a provisional standard for the comparison of gravimeters employed by the Observatory. In 1953 it was considered that the usefulness of this line as a suitable reference standard for eastern Canada might appreciably be increased by extending its range. Accordingly a gravimeter program was initiated the following summer to establish a series of stations between Maniwaki and Senneterre, Quebec (see Fig. 1).

About the same time a redetermination with modern pendulum equipment was being carried out [*Garland*, 1953, 1955; *Rose* and *Woollard*, 1955], between the National Reference Stations of Canada and the United States, the former being located at the Dominion Observatory in Ottawa and the latter in the building of the Department of Commerce in Washington, D. C. It was decided therefore to abandon for the time being the program of measurements north of Ottawa and to concentrate on extending the calibration line south to include observations at important gravity stations in Washington. The objectives of this plan, although not entirely independent of each other, were three-fold: (1) to establish a highly reliable line of gravimeter stations between Ottawa and Washington (involving a change in gravity of about 500 mgal) to serve as a suitable, readily accessible gravity reference standard; (2) to provide an independent measure of the Ottawa-Washington gravity difference; and (3) to assess the reliability of the new pendulum determinations. This investigation has been satisfactorily

completed and a detailed account of the results follows.

The measurements—The measurements were made with three instruments: North American Gravimeter 137, North American Gravimeter 85, and Worden Gravimeter 44. Complete forward looping procedure, the scheme being that stations A, B, C, for example, are occupied in the order A-B-A-B, B-C-B-C, etc., was followed for all measurements. The distances between successive stations were kept sufficiently small, less than 30 miles on the average, to permit an accurate estimate of zero drift for each instrument and at the same time to allow exclusive use of the short range dial of the Worden instrument.

The gravimeter observations were carried out on three separate observing programs, in October 1954, August 1955, and November 1955. Each program involved a complete coverage of the line between Ottawa and Washington and required about ten days' time and 2500 miles of automobile travel. By observing with three gravimeters concurrently at all stations it was hoped to obtain three independent sets of results from each observing program which could be matched to provide reliable values of gravity.

Descriptions of stations—In Ottawa, the National Reference Station for Canada has for many years been defined as the upper surface of a cement pier located in Room No. 2 in the basement of the Dominion Observatory. All relative gravity measurements within Canada have been based on a value of 980.622 cm/sec^2 for this station, obtained by direct comparison with Potsdam in 1928 [*Miller*, 1931]. The geodetic coordinates and height of the pier (referred to Geodetic Survey of Canada bench mark 125-A) are 45° 23′ 38.4″ N, 75° 42′ 56.4″ W, and height 271.68 feet.

In 1954 the gravity division was transferred from the Observatory building to the new Geophysical Laboratory (see Fig. 2 and 3). Although all future pendulum work is to be carried out in the Geophysical Building, the site of the original pendulum pier in the Dominion Observatory will continue to serve as the National Reference Station for Canada.

The new site for pendulum measurements is located in a temperature controlled room (Room 8) in the basement of the Geophysical Laboratory. The pendulum pier which is four feet square is situated in the center of the room, with its upper surface at floor level. It is made of concrete set about seven feet in subsoil, and has no contact with the surrounding basement floor. The geodetic coordinates of the new pendulum pier are 45° 23′ 41.9″N, 75° 42′ 52.9″W, and height 257.14 feet.

Two gravimeter stations in the vicinity of the Dominion Observatory have been well connected

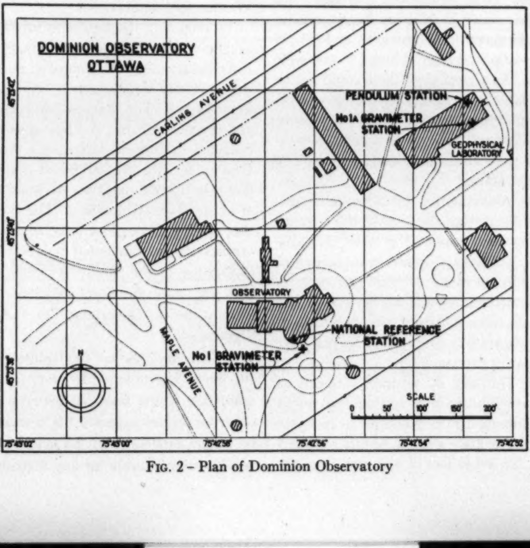

FIG. 2 – Plan of Dominion Observatory

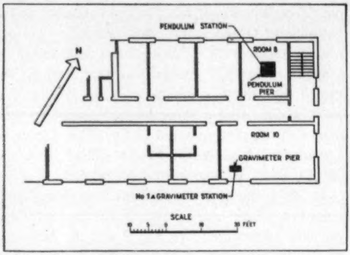

FIG. 3 – Plan of Geophysical Laboratory

to the National Reference Station. These subsidiary sites have proved convenient for international gravimeter ties and for control of local surveys. Gravimeter Station 1 is located in the center of the cement apron immediately outside the main entrance to the Dominion Observatory building. Its coordinates are 45° 23′ 38.2″ N, 75° 42′ 56.2″W, and height 274.22 feet.

Gravimeter Station 1A is the upper surface of a cement pier in the southwest corner of Room 10 in the basement of the Geophysical Laboratory (see Fig. 3). Its geodetic coordinates are 45° 23′ 41.6″N, 75° 42′ 52.8″W, height 259.44 feet.

Between Ottawa and Washington, apart from the differences of gravity involved, accessibility for observation using automobile transport was the chief criterion used in selecting the gravimeter sites. On the first trip to Washington in 1954, 27 intermediate stations were established to complete the connection. As a number of these could not be recovered on later trips because of new construction, local traffic disturbances, etc., it was necessary to establish new stations. As a result a total of 35 stations were established during the course of the three operations.

To facilitate re-occupation by other investigators diagrams illustrating the sites of the gravimeter bases have been drawn (Fig. 4–6). The distances to the gravimeter bases from points of reference, usually portions of buildings such as post offices, churches, schools are shown in the diagrams. While these distances are nearly exact, neither the configuration of the buildings nor their scale is necessarily precise.

The results—The lack of accurate connections between sites of fundamental stations has often led to much uncertainty in attempts to compare and evaluate the relative gravity results of different observers. To avoid loss of accuracy in correlating data the important Ottawa sites described above have been interconnected with great accuracy. In addition ties have been made to the laboratories of the National Research Council of Canada, both the Sussex Street laboratory where absolute measurements of gravity are in progress, and the Applied Chemistry building on the Montreal Road. The results of these connections are summarized schematically in Figure 7. The probable error of each gravity difference, estimated from the closure errors of the two closed circuits, is ± 0.03 mgal. The adopted values for the Ottawa sites on the basis of these results are given in Table 1.

Gravity differences between Ottawa and Washington are summarized in Table 2 which shows the results between Gravimeter Station 1 in Ottawa and Gravimeter Station 37, near the main entrance of the East Building of the National Bureau of Standards in Washington. To permit an independent evaluation of the measurements and to facilitate later revision, should this be necessary, a complete list of the gravity differences observed with each instrument is given. The stations between which the gravity differences have been measured are indicated in the first column and may be identified by reference to Table 3. A total of 36 gravity intervals have been determined, but as pointed out previously, only 27 segments are required, on the average, to complete the Ottawa-Washington connection.

To eliminate discrepancies arising from inconsistencies in calibration, the results of the three instruments have been compared over the complete range of the measurements, using a method of least squares. The statistics of these comparisons are given in Table 4. The gravity differences obtained in August 1955 using North American Gravimeter No. 137 and based upon a calibration factor of 0.23916 mgal per division, were accepted as a provisional standard. The justification for this will be given in a later section. The uncertainties of the calculated values of the relative calibration factors are very small, all less than 0.01 pct, and therefore contribute a negligible amount to the uncertainty in the final gravity differences.

Agreement between the values obtained with the three instruments is very satisfactory. Examination of the residuals between standard and observed values suggests the remaining errors to be purely random, with no marked suggestion of non-linearity of scale for any instrument over the

range of the measurements. The standard deviations of a single observation, as determined from the residuals from the mean of repeated measurements, are listed for each instrument. These results indicate that generally the behavior of each gravimeter was much the same throughout all three periods of observation. The Worden instrument, however, may be an exception, as the results of the two 1955 runs have twice the uncertainty of the 1954 measurements. The better quality of the observations and possibly the larger calibration factor obtained for this instrument in 1954 may be related to the fact that the instrument was temperature controlled during the period of these measurements, but not during the later calibrations. A complete analysis of the performance of the gravimeters employed during these measurements is being carried out by R.L.G. Gilbert of the Dominion Observatory and will be reported separately.

On the average the uncertainty of the observations with North American Gravimeter 85 is about twice as great as that of the other two instruments. Therefore in forming the mean grav-

ity differences tabulated in Table 2, the Worden gravimeter values and those of North American 137 have each been assigned a weight of 4 while those of North American 85 have been given a weight of 1.

Before adopting the final or adjusted differences in gravity it was necessary to take account of the fact that 24 of the gravity intervals form five closed networks (Table 2) which required adjustment for closure. Although these errors are quite small and have rather a minor effect on the final values, they have been eliminated by a graphical method [*Smith*, 1951] of least squares. The final values of gravity for all stations, based upon these adjusted measurements and a value of 980.62200 for the National Reference Station in Ottawa, are given in Table 3.

Discussion of results—Before comparing these results with those of other investigators it is desirable to estimate the practical limits of error in forming the total Ottawa-Washington difference. In doing this, errors both of the random and systematic variety must be considered.

The random errors, which are believed to be chiefly observational, may be estimated with considerable accuracy from the standard errors of the individual gravity segments. The latter, estimated from the residuals in forming the weighted mean differences (Table 2) are extremely small and in no case exceed 0.02 mgal. Their contribution to the total error will increase as the square root of the number of segments. Assuming, therefore, that a maximum of 36 gravity intervals are required to complete the Ottawa-Washington connection, the uncertainty arising from random errors should not exceed ±0.12 mgal.

An estimate of the systematic error resulting from uncertainty in the absolute calibration of the gravimeters is somewhat more difficult. As previously mentioned the gravity differences depend fundamentally upon a calibration factor of 0.23916 mgal per division for North American Gravimeter 137. This calibration in turn depends upon the results of measurements carried out during July and August of 1955 to strengthen the primary gravimeter network across southern Canada. Aircraft transportation was employed and stations established at principal airports by looping with three gravimeters. The results of this investigation, which provide a provisional datum for the adjustment of most regional gravimeter work completed in Canada, are based upon comparisons against six Cambridge pendulum station values [*Garland*, 1953, 1955], not including Washington, over a gravity range of about 800 mgal. The statistics indicate that the resulting calibration should be accurate to at least one part in four thousand. Over the difference in gravity between Ottawa and Washington the corresponding uncertainty would be ±0.13 mgal. The total error from both random and systematic errors is therefore estimated to be ±0.25 mgal.

While these results appear sufficiently reliable, there is a possibility that systematic errors caused by inaccurate absolute calibration have been under-estimated. The chief difficulty arises from recently published results [*Garland* and *Tanner*, 1957] of a calibration carried out for the North American Gravimeter 137 in August 1954, also by comparison with Cambridge pendulum values in Canada but over a higher range (990 mgal total). This calibration was completed during the latter part of the field season, about two months before the first calibration run (October 1954) was carried out between Ottawa and Washington. The value obtained, 0.24199 ± 0.00012 mgal per division, indicates that the October 1954 calibration (Table 4) should be increased by about 0.13 pct. This would suggest that a value of −502.1 mgal for the Ottawa-Washington difference might be more correct than the one (−501.4 mgal) indicated in the present work. More serious still is the effect that a larger calibration factor would have

on the results of recent comparisons between the North American and European gravity networks (unpublished work of Morelli, Innes, and Rice). In this investigation it was found that over a range of 700 mgal the European gravity standard and that employed by the Dominion Observatory agree within 0.03 pct. To accept the larger value suggested by the Garland-Tanner investigation

would indicate a much larger disagreement (0.15 pct) between the currently adopted standards.

Although no satisfactory explanation can yet be offered to account for the large discrepancy between the independent calibrations obtained in 1954, an investigation is now in progress in an attempt to determine whether it might result from (1) instrumental defects such as non-linearity of scale, change in calibration due to overheating, etc., (2) different observational procedures used during the calibration. (For example, the August 1954 calibration [*Garland* and *Tanner*, 1957] is based upon standard looping procedure south of Edmonton. To the north, however, the results depend on measurements taken at consecutive airports on a single return trip between Edmonton and Whitehorse involving a period of 36 hours. Unpublished results of an investigation by Gilbert show that the two methods of calibration do not necessarily give the same result), (3) inconsistencies in pendulum station values over which the instrument was calibrated. The results of this investigation will be reported separately.

Comparison with the results obtained for the Ottawa-Washington difference by other investigators, while not altogether resolving the difficulty because of disagreement between the various sets of measurements, nevertheless gives considerable assurance that the presently adopted standard is satisfactory. Table 5 summarizes recently published results for this difference obtained with the Cambridge [*Garland*, 1953; *Garland* and *Cook*, 1955] and Gulf [*Woollard* and others, 1956] apparatus. The actual observed differences as well as the corrections used to adjust them to the National Reference sites for easy comparison have been included.

	Nov. 1955	0.111194±0.000008	24	±0.04	Calibration altered during repairs Sep. 1955.

[a] Oct. 1954 measurements observed by L. G. D. Thompson and A. M. Bancroft; Aug. 1955 measurements observed by R. L. G. Gilbert and L. G. D. Thompson; Nov. 1955 measurements observed by J. G. Tanner and R. L. G. Gilbert.

Examination of the table shows that the gravimeter results of this investigation are in excellent agreement with the mean of all the pendulum results (−501.5 mgal). When considered separately it is found that they agree much more favorably with the Gulf pendulum results than with the Cambridge pendulum values. The Gulf pendulum determination differs by only 0.3 mgal, which is about equal to the accuracy estimated for the gravimeter measurements.

The mean value of the Cambridge pendulum determinations is almost in exact agreement with the present gravimeter result. This fact, however, does little towards proving the correctness of the gravimeter results for not only do the separate pendulum determinations seriously disagree with each other (2.9 mgal) but with the gravimeter results as well. The earlier results [*Garland*, 1953] were rejected in a final adjustment [*Garland* and *Cook*, 1955] because of suspected instability in the site of the measurements in Washington. Regarding the latter determinations the present gravimeter result is the greater by 1.4 mgal. This is much too great, and in the opposite direction, to be attributed to calibration uncertainties, and therefore casts doubt on the accuracy of the final determination of the Ottawa-Washington difference using the Cambridge pendulums. This conclusion is supported by recently published results [*Cook*, 1957] of a comprehensive analysis of a large number of Cambridge pendulum measurements. It was shown that the standard deviations of the gravity differences of Ottawa and Washington from Teddington have a standard deviation of about 1 mgal.

In view of the lack of agreement between the various sets of pendulum data there seems little merit at this stage in attempting an overall adjustment in which both pendulum and gravimeter results are incorporated. A more urgent requirement is that more pendulum work be carried out. We therefore look forward with great interest to the results of pendulum work recently completed by L. G. D. Thompson of the Dominion Observatory, using a newly constructed bi-pendulum apparatus [*Thompson*, in press]. New measurements have been carried out not only in Ottawa and Washington but at several intermediate points. When these results are available a complete adjustment will be possible in which all data will be incorporated, not only the work reported here but the results of several other base looping programs carried out over the Ottawa-Washington interval in 1956 and 1957.

Summary and conclusions—The most important contribution of this work is the successful development of a gravity standard for eastern Canada and the United States. The 36 gravity segments which connect the National Reference stations of these two countries have been accurately determined, although some uncertainty still remains in placing the measurements on an absolute basis. The present determination for the difference in gravity between Ottawa and Washington compares favorably, within 0.3 mgal, with recent Gulf pendulum measurements, but disagrees quite seriously with each of the two determinations

carried out with the Cambridge apparatus. Pendulum measurements now in progress by the Dominion Observatory are expected to throw further light on this subject.

The internal consistency of the present measurements appears highly satisfactory and this line of stations should serve not only as a satisfactory standard for calibration purposes, but also enable an accurate evaluation of future pendulum determinations. The random error of each gravity difference is estimated to be less than 0.02 mgal which would suggest that over the complete Ottawa-Washington range, 501.4 mgal, the uncertainty is about 0.1 mgal, or one part in five thousand.

Acknowledgments—The writer wishes to acknowledge his indebtedness to various members of the Gravity Division of the Dominion Observatory who have contributed to this paper. The measurements were made by L. G. D. Thompson, R. L. G. Gilbert, J. G. Tanner, and A. M. Bancroft in connection with the standardization of gravimeters to be used on regional surveys, while the greater part of the mathematical analysis has been carried out by P. R. Ryan. In addition, the writer wishes to thank officials of the United States Coast and Geodetic Survey and of the National Bureau of Standards for their courtesy and cooperation during the course of the measurements in the United States.

Tropospheric Bending of Radio Waves

L. J. ANDERSON

Abstract—A simple and accurate method is presented for computing the refractive bending of radio waves in the lower 100,000 ft of the atmosphere. A given refractive-index profile is approximated by a series of straight lines (layers of constant gradient) and the incremental bending computed for each layer.

The method is applied to the 'standard' atmosphere, and total bending is plotted against the surface refractive index for various vertical angles of arrival from 0 to 1 radian.

Introduction—The bending of radio waves in the troposphere is important in radio astronomy problems, as well as in the precise location by radar of high-altitude aircraft and other targets. Such bending increases rapidly as the angle of arrival approaches grazing incidence, and can amount to a degree or more in many cases. Frequently, it is at these low angles that precise location is most important.

The method described below was developed for computing total tropospheric bending as a function of angle of arrival and refractive-index profile parameters in a simple and rapid way, that retains the accuracy and flexibility of existing techniques. Pearcey [*Pawsey* and others, 1947] developed a simple method for making such computations assuming a linear decrease of refractive index from the surface value to unity at a height of five miles (8 km). Allowance for atmospheric changes was made only by changing the overall gradient. *Schulkin* [1952] describes a method for handling any refractive-index profile by approximating it with a series of straight lines. Thus, the atmosphere is divided into layers, each with a constant refractive-index gradient. The approximation can be made as good as one pleases by using enough layers. His method involves finding an average value for the angle of incidence of the ray in each layer. The numerous computational steps involved, including square roots and averaging, are straightforward, but somewhat tedious.

The method described below uses the same general approach assuming constant-gradient layers, but the procedure is simplified so that each step may be performed graphically, thereby avoiding all computing except simple addition, subtraction and interpolation.

Development of the method—Consider an atmospheric layer of infinitesimal thickness dh (Fig. 1) at height h above the Earth's surface, with a ray passing through the layer at an angle α with the horizontal. If the vertical refractive-index gradient is dn/dh, we can write

$$\begin{aligned} d\alpha &= \frac{dn}{dh}\frac{\cos\alpha}{n}\,(dh/\sin\alpha) \\ &= \frac{dn}{dh}\cot\alpha\,dh \end{aligned} \tag{1}$$

since n differs from unity by at most one part in 2500.

From Snell's law for spherical stratification we have

$$n(a + h)\cos\alpha = n_0 a \cos\alpha_0 \tag{2}$$

where n is the refractive index at height h; a is the radius of the Earth, n_0 and α_0 are the refractive index and the angle of arrival, respectively, at the Earth's surface. Solving (2) for cot α and substituting in (1) gives

$$\begin{aligned} \gamma &= \int_0^h d\alpha \\ &= \int_0^h \frac{dn}{dh}\frac{dh}{\sqrt{\sin^2\alpha_0 - 2(n-1) + 2h/a}} \end{aligned} \tag{3}$$

The atmosphere, as mentioned previously, is assumed to consist of layers, each with a constant refractive index gradient ($dn/dh = k$).

Thus the incremental bending $\Delta\gamma$ for one layer becomes

$$\Delta\gamma = k\int_h^{h+\Delta h}\frac{dh}{\sqrt{\sin^2\alpha_0 - 2h\left(k - \dfrac{1}{a}\right)}} \tag{3}$$

$$= \frac{ka}{1 - ka}\sin(\beta - \alpha_0) \tag{4}$$

where β is the angle at which the ray emerges from the layer (Fig. 2).

Both β and α_0 can be rather large (almost 1600 milliradians for vertical incidence), but their difference is always less than 20 milliradians. Our problem then is to compute this small difference.

If we consider a straight ray emerging from the layer at an angle α (Fig. 2), such a procedure is readily found.

TABLE 1 – *Sample computation of bending in standard atmosphere*

Height	α_0	$\alpha - \alpha_0$	α	Δn	$\alpha - \beta$	$\beta - \alpha_0$	k	$\Delta\gamma$
ft × 10^3	mr	mr	mr	n	mr	mr	units/ 1000 ft	mr
0–15	0	21.9	21.9	66	3.4	18.5	13.2	7.30
5–10	18.5	10.0	28.5	53	1.9	8.0	10.6	2.30
10–15	26.5	7.8	34.3	42	1.3	6.5	8.4	1.29
15–20	33.0	7.0	40.0	35	0.88	6.1	7.0	1.00
20–30	39.1	10.5	49.6	52	1.07	9.4	5.2	1.07
30–40	48.5	8.8	57.3	34	0.62	8.2	3.4	0.60
40–50	56.7	7.7	64.4	24	0.35	7.4	2.4	0.36
50–60	64.1	7.9	71.0	15	0.21	6.7	1.5	0.22
60–100	70.8	22.8	93.6	24	0.26	22.5	0.6	0.29
Total. . . . . γ =								14.43

Substituting $n = n_0 - \Delta n$ in (2) we can write

$$(1 - \Delta n)\,(1 + \Delta h/a)\cos\beta = \cos\alpha_0 \tag{5}$$

for the refracted ray, and

$$(1 + \Delta h/a)\cos\alpha = \cos\alpha_0 \tag{6}$$

for the straight ray.

Noting that α is a function only of layer thickness Δh and α_0, we can plot $\alpha - \alpha_0$ as a function of these two variables, as in Figure 3. Substituting (6) into (5) we have

$$(1 - \Delta n)\cos\beta = \cos\alpha. \tag{7}$$

Similarly, β is a function only of Δn and α, and we plot $\alpha - \beta$ as a function of two variables in Figure 4. We now can determine $\beta - \alpha_0$, since

$$\beta - \alpha_0 = (\alpha - \alpha_0) - (\alpha - \beta)$$

TABLE 2 – *Computed bending in the lowest 10,000 ft of a standard atmosphere*

Δh	$\Delta\gamma$	Δh	$\Delta\gamma$	Δh	$\Delta\gamma$
ft × 10^3		ft × 10^3		ft × 10^3	
0–10	8.90	0–5	7.30	0–1	3.50
				1–2	1.33
		5–10	2.30	2–4	1.85
				4–6	1.32
				6–8	1.00
				8–10	0.79
Total γ. . .	8.90 mr		9.60 mr		9.79 mr

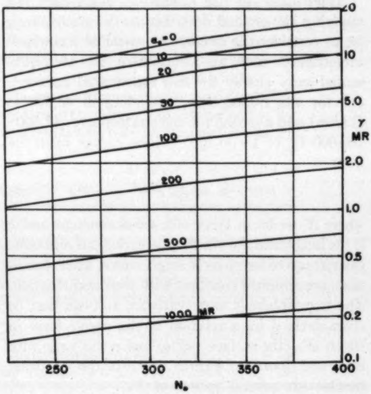

FIG. 7 – Total ray bending in the standard atmosphere

The final step is to solve for $\Delta\gamma$ in terms of $k = \Delta n/\Delta h$ and $(\beta - \alpha_0)$ by representing (4) in graphical form. This is done in Figure 5.

For the second layer, α_0 is the same as β from the bottom layer. Using this new α_0 we repeat the process with values of Δh and Δn applicable to the second layer. After carrying the process to as high a level as we wish, the total bending is simply the sum of the $\Delta\gamma$'s for all layers.

Discussion—In plotting Figure 3, a number of values of layer thickness Δh were used ranging from 100 ft to 100,000 ft (30.5 m to 30.5 km). Interpolation between these curves, as well as those in Figures 4 and 5, is done with a strip of logarithmic paper with cycle length matching the figures. In Figure 4 several values of Δn in units $\times\ 10^{-6}$ are plotted. Positive values refer to the normal case of downward refraction. The dashed curves labeled with negative Δn's are for substandard layers. In this case the ordinate is also negative, that is, β is larger than α. The parameter k in Figure 5 is expressed in terms of a unit representing the increment of n per thousand feet of h. Again, positive k's refer to downward refraction. Negative k's are designated by the short dashes. In this case $\Delta\gamma$'s are also negative. When k exceeds 48 units/1000 ft, the denominator of (4) becomes negative, but $\beta - \alpha_0$ simultaneously becomes negative, hence $\Delta\gamma$ remains positive, as one would expect. The long dash lines refer to this situation when $\beta - \alpha_0$ is taken as negative.

Application to the standard atmosphere—In applying the method described to the atmosphere, let us consider the average or so-called 'standard' atmosphere. Such an atmosphere can be represented very closely by two exponential curves—one for the troposphere, extending to 42,500 ft (13 km) and a second for the stratosphere (42,500–100,000 ft, or 13–30 km). These curves have the form

$$N = N_0 e^{-ch} \tag{8}$$

where $N = (n - 1) \times 10^6$, c is a constant and h is the height. In the stratosphere, one can represent the refractive index by a single curve, since conditions are assumed constant with time and location. The troposphere is more variable, and can best be characterized by a relation of the above form in which N_0 (the surface value) and c will vary with time and location. Figure 6 shows the resulting profiles for several values of N_0.

Table 1 shows the application of the computing method to the atmospheric model shown in Figure 6, for $\alpha_0 = 0$ and $N_0 = 350$. It will be seen that a total of nine layers are used to approximate the exponential profiles up to 100,000 ft.

In order to test the validity of this approximation, the lowest 10,000 ft (where $\frac{3}{4}$ of the bending occurs) was divided into 1, 2, and 6 layers. The results are compared in Table 2. It can be seen that dividing this portion of the column into more than two layers makes little change in the resulting γ.

In Figure 7, the total bending γ is plotted against N_0 for various values of α_0 using the procedure shown in Table 1, and the profile representation of Figure 6.

Seasonal Changes in Day-to-day Variability of Upper Air Winds Near the 100-km Level of the Atmosphere

E. H. VESTINE

Abstract—The dynamo theory of the magnetic daily variation predicts that winds flowing within the E region at a height of roughly 100 km generate a world-wide electric current system at this level. The electric currents are generated mainly in middle and high latitudes by the horizontal motion of electrically conducting air across the radial component of the geomagnetic field. Near the equator the geomagnetic field is horizontal so that according to the theory the current above the equator must result from an electrostatic field directed from west to east and overhead near noon, closing the current circuit. The theory also implies that this horizontal electric field must extend to the highly rarefied F region, which will be lifted bodily upwards in response to the crossed electric and magnetic field. Hence day-to-day differences in middle latitude winds may be reflected, according to the theory, in day-to-day differences, in heights, and hence in ion-densities of the F region, measured by radio methods.

The day-to-day differences in ionospheric F region critical frequencies near noon are studied as a measure of corresponding differences in the wind-generated ionospheric electric field at the magnetic equator. These changes in F region critical frequencies reflect corresponding changes in height of the F region, caused by the electric field of the daily variation. It is shown that the daily variation, though proportional to both the electric field and the electric conductivity, is probably a good indicator of day-to-day changes in wind speeds in the E region. The data do not support the view that the ionizing solar radiation fluctuates much from one day to the next. This is in accord also with statistical results obtained by Forbush for solar flares and their effects upon the daily variation. The day-to-day changes in wind speed indicated for the E region in middle latitudes are found to be largest in northern winter, and least in northern summer, and are discussed in relation to evidences of variability dependent on season noted from meteorology for tropospheric winds. Changes in wind speed with sunspot cycle are also discussed.

The average magnitude of the daily magnetic variation shows a high correlation with sunspots (as high as 0.99 for yearly averages). Thus, having eliminated electric conductivity of the E region as an important cause of the day-to-day variability in the magnetic variation, the wind speed in the E region must be able to change by a factor of two or more from one day to the next, as a consequence of solar events.

Introduction—In recent years, considerable observational evidence has been accumulating respecting the air flow within the ionosphere [*Briggs* and *Spencer*, 1954; *Mitra*, 1949; *Salzberg* and *Greenstone*, 1951]. These data arise from directly observed motions of meteor trains, noctilucent clouds, and inferences based upon radio wave reflections and scintillations [*Kellogg* and *Schilling*, 1951; *Manning*, *Villard*, and *Peterson*, 1950; *Ryle* and *Hewish*, 1950; *Whipple*, 1954; *Kallmann*, 1955; *Clemmow*, *Johnson*, and *Weekes*, 1955; *Jesse*, 1896; *Störmer*, 1935; *Vestine*, 1934; *Pant*, 1956]. Inferences have also been made on the basis of the dynamo theory of the magnetic daily variations [*Chapman*, 1919; *Vestine*, in press; *Forbush*, 1956; *Maeda*, 1955b; *Kato*, 1956; *Baker* and *Martyn*, 1953; *Martyn*, 1947]. The height of the current layer responsible for the solar daily magnetic variation seems measured to be near and within the E region of the ionosphere, as noted by a magnetometer aboard a rocket [*Singer*, *Maple*, and *Bowen*, 1951]. Similar indications are shown also by height and ion-density measurements of the E region [*Appleton* and *Lyon*, 1957; *Appleton*, 1955]. There now appears little doubt that the magnetic daily variations are due to the dynamo action of winds, in which emf's are produced by the motion of electrically conducting air across the geomagnetic field.

The magnetic daily variation observed at ground level will depend both upon the dynamo electric field and the electric conductivity; if the electric conductivity varies more slowly than do the winds with time, the amplitude of the daily magnetic variation may provide useful indications of the day-to-day fluctuations of the upper air winds in the E region. In particular, it would appear from studies by *Hirono* and *Maeda* [1954], and *Baker* and *Martyn* [1953; also *Martyn*, 1947], that the abnormally large diurnal variation at Huancayo, Peru, on the magnetic equator, is associated with an electric field generated mainly by broadly distributed winds circulating within the E region in middle and high latitudes. Near noon this electric field will have a lifting action upon the F region [*Baker* and *Martyn*, 1953; *Martyn*, 1947]; the day-to-day effects upon F-region height and critical frequency may hence provide a useful indicator of the day-to-day changes in the electric current generating winds flowing in middle latitudes distributed in height near and within the E region. The effects noted for the F region of course will be independent of electric conductivity of the E region as noted near the magnetic equator [*Shimazaki*, 1956; *Sato*, 1956].

It is the purpose of the present paper to provide such estimates of possible day-to-day variability in upper-air winds within the E region using observed data on the magnetic daily variation and height of the F region at the magnetic equator (actually using as indicator the height-sensitive critical frequency of penetration for radio waves). This is done for all days of the years 1938–1945 inclusive, for Huancayo, Peru. The marked seasonal effects noted show changes in kinetic energy which call to mind effects estimated for wind fluctuations in the lower atmosphere by *Mintz* and *Dean* [1952]. Changes in day-to-day wind speeds with sunspot cycle are scarcely detectable, so that it is inferred that the substantial increase in the amplitude of the solar magnetic daily variation with sunspot cycle is probably mainly a gradual electric conductivity effect, together with a general increase in generating wind speed, which appears to be gradual only in successive averages taken over many days. Finally, propagation of meteorological disturbances upwards from the stratosphere is mentioned in relation to the observed day-to-day changes in wind speeds in the E region.

The amplitude of the solar daily magnetic variation S_q—*Bartels* [1946] has listed the daily amplitudes of the solar daily magnetic variation S_q at Huancayo, expressed in terms of a convenient index called δW_2. (The value δW_2 measures the departure from the amplitude of S_q appropriate to an arbitrary sunspot number $R = 50$, chosen thus for statistical convenience; it is hence sometimes positive, sometimes negative. The units of δW_2 are chosen so that the standard deviations for sunspots R and for δW_2 are about 25 each, which makes the appropriate unit for δW_2 about two gammas; one gamma = 10^{-5} cgs.)

The daily measures δW_2 are of special interste because of their high average correlation with sunspot numbers R. Bartels found this correlation factor to be +0.930 for monthly averages, 0.969 by seasonal averages, and +0.988 for annual averages.

In the absence of substantial fluctuations in electric conductivity, δW_2 may provide an effective indicator of upper-air winds which are highly correlated on an average with sunspots.

The change in δW_2 with season—In the present paper the day-to-day differences in δW_2 defined as $\Delta\delta W_2$, say, are of special interest in relation to similar differences in noon critical frequencies for the F_2 region. The day-to-day change may be written $\Delta\delta W_{2,S} = 0.4\omega_1(A_S - A_{S-1})$ for the Sth day in a sequence, where ω_1 is a number used by Bartels to adjust for seasonal changes, and A_S the difference between the field in horizontal magnetic intensity at Huancayo averaged for some hours near and at noon, and for some hours near and at midnight. The respective monthly values of ω_1 used by Bartels in the sequence beginning with January were: 1.04, 0.90, 0.82, 1.13, 1.43, 1.36, 1.79, 1.30, 1.02, 0.88, 0.94, and 1.00. It will be seen that ω_1 is a monthly parameter designed to standardize values for each month. It varies from 1.79 for July to 0.82 in March, for the years considered by Bartels. Hence these numbers of Bartels designed to measure solar wave radiation may also be used in the study of terrestrial seasonal effects. In the case of noon values of f_0F_2, convenient tabulations for the purpose are provided in the ionospheric publication for Huancayo [*Wells* and *Berkner*, 1947].

Before discussing the magnetic and ionospheric results more fully it may be helpful to consider the present status of the dynamo theory of the magnetic daily variation.

Some details of the dynamo theory of S_q—Although there has been considerable discussion of the atmospheric circulation within the E region, in relation to production of S_q, there remains considerable doubt respecting quite important features of this circulation. The main driving forces are often assumed to be tidal, although suggestions have appeared ascribing to atmospheric heating [*Sen* and *White*, 1955; *White*, 1956; *Siebert*, 1956] effects 20 or more times as great as that of the tides. *Wulf* [1945] has presented other arguments stressing the dominant importance of solar heating. At the present time there does not appear to be any clear cut way of resolving this matter of the relative importance of tidal and heating action. Since the resonant action enhancing the tides is in fact temperature sensitive, it is especially difficult to separate the influence of each causative factor. The day-to-day variability of S_q suggests that there are considerable changes in the wind patterns from one day to the next, so that it may be argued therefore that there appear important differences from one day to the next in the winds, and consequently also either in the heating or tidal effects [*Chapman* and *Bartels*, 1940; *Uyeda*, 1949; *Chapman* and *Stagg*, 1929, 1931].

As *Ota* [1949] has shown from the daily magnetic variations observed at many stations of the year 1932–33, the center of both the northern and southern current vortex of the overhead current system for S_q shifts in latitude with month of the year. He showed also that these changes were of the order of about ten degrees latitude with month and season, and that they were different in America, Europe, and the Far East. He also found similar differences existed from day-to-day in extension of earlier studies of *Hasegawa* [1936].

According to the dynamo theory, these day-to-day differences in current system could arise either from daily changes in the upper-air circulation, or changes from day to day in the distribution of ions and electrons throughout the E region. In order to examine this more closely suppose E at any point is the horizontal electric field driving the current system, and that it comprises a dynamo electric field E_i and an electrostatic field E_s (*Chapman*, 1919; *Vestine*, in press; *Forbush*, 1956; *Chapman* and *Bartels*, 1940]. Then

$$\left.\begin{aligned} E_x &= E_{sx} + E_{ix} \\ E_y &= E_{sy} + E_{iy} \end{aligned}\right\} \qquad (1)$$

where x, y indicate components directed to the south and east, respectively.

If S is the electrostatic potential and u, v are the southward- and eastward-directed winds

$$\left.\begin{aligned} E_x &= -\partial S/a\partial\theta + vH_z \\ E_y &= -\partial S/a \sin\theta\partial\lambda - uH_z \end{aligned}\right\} \qquad (2)$$

where $H_z = -C\cos\theta$ is the vertical component of the terrestrial centered dipole. If ϕ is the velocity potential, $u = -\partial\phi/a\partial\theta$, $v = -\partial\phi/a\sin\theta\partial\lambda$ so that (2) may be written

$$\left.\begin{aligned} aE_x &= -\partial S/\partial\theta + C\cot\theta\partial\phi/\partial\lambda \\ aE_y &= -\partial S/\sin\theta\partial\lambda - C\cos\theta\partial\phi/\partial\lambda \end{aligned}\right\} \qquad (3)$$

hence eliminating S

$$\begin{aligned} &\cot\theta\frac{\partial^2\phi}{\partial\lambda^2} + \frac{\partial}{\partial\theta}\left(\sin\theta\cos\theta\frac{\partial\phi}{\partial\theta}\right) \\ &\qquad = \frac{a}{c}\left\{\frac{\partial E_x}{\partial\lambda} - \frac{\partial}{\partial\theta}(E_y\sin\theta)\right\} = F(\theta,\lambda) \end{aligned} \qquad (4)$$

If ϕ comprises typical surface harmonics

$$\phi_n^m = (k_{n,a}^m \cos m\lambda + k_{n,b}^m \sin m\lambda)\, P_n^m(\cos\theta)$$

where $P_n^m(\cos\theta)$ is the normalized spherical function of Schmidt, and λ the local time. Then the left hand side of (4) becomes

$$\sin\theta\,(k_{n,a}^m \cos m\lambda + k_{n,b}^m \sin m\lambda)\, G_n^m(\theta)$$

where

$$\begin{aligned} G_n^m(\theta) = &-\frac{1}{2n+1} \\ &\{[(n+1)^2 - 1][(n+1)^2 - m^2]^{\frac{1}{2}} P_{n+1}^m \\ &\qquad + [n^2 - 1][n^2 - m^2]^{\frac{1}{2}} P_{n-1}^m \end{aligned} \qquad (5)$$

The right-hand side of (4) is also expressible in surface harmonics, and is derived from the total electric field E. This electric field can be derived approximately from the magnetic field at ground level taking the horizontal part of this as $2\pi i$, where i is the current crossing unit width as a part of the current-system overhead. *Maeda* [1955a, 1956] has used such values $i = \sigma E$ where σ is the integrated electric conductivity, σ being estimated taking zenith angle of the sun as ionizing source into account. He derived the first three Fourier terms of the variation of E_x and E_y with latitude and obtained the spherical harmonic coefficients of Φ listed in Table 1, listed according to their order m and degree n.

It is clear that the main term is diurnal, and that next in (about equal) importance are the terms in P_2^2 and P_3^2.

The corresponding result for the distribution of the wind velocity and total electric field is shown in Figures 1 and 2, respectively. Actually, the suggested amplitude of the diurnally varying wind component is about 30 m/sec, the semi-diurnal part being about 10 m/sec, in low latitudes. These results will be useful later in a statistical study.

The electrostatic field which serves to close the current circuit, as estimated by Maeda, is mapped in Figure 3. This electrostatic field extends also to the F region, since there will be some horizontal separation of charge in the E region, and yields a vertical drift velocity at the F region of $W = (E_y/F) \cos I$ where I is the magnetic dip angle, F the total magnetic intensity, and E_y the eastward directed electrostatic field. Taking $F = 0.27$, the change in height dh per second may be written approximately as $dh = (E_y/0.27) \cos t\, dt = 0.13\, E_y \cos (2\pi t/24)\, dt$, where t is measured in hours. The change Δh in height from 06h to 12h is then found on integration to be $0.13\, E_y$.

The observed average increment in height for years of various sunspot number R from 06h to 12h is available from tables of the results of observations at Huancayo. Table 2 lists the average increments for the 6-hour period for h', the virtual height of reflection for radio waves. Also included are values for h_m, the estimated height of maximum electron density, for various years.

Since observed values of A_S (the range in S_q) were not available for 1948, values for all years are calculated from the approximate relationship derived for earlier years, namely, $A_S = 64 + 0.64\, R$. On the other hand the value $A_S \sim 2\pi i = 2\pi k E_y$, where k is the effective electric conductivity, so that having estimated E_y from height data the value k for the various sunspot averages R can be estimated. The results are shown also in Table 2, where the increase in k with R is expressible approximately as $k = 0.012 + 3.1 \times 10^{-5}R$, provided the dynamo electric field is zero or negligible at Huancayo, and that only the electrostatic field contribution is effective. If this is true, the increase in k from 0.013 to 0.017 from 1942–44 to 1948 is about 30 pct for a change in R from 19 to 141. This is less than the 50 pct increase obtained from critical frequencies for this range in R, based upon observed data at the equinoctial months. This discrepancy is substantial, but might possibly be reduced if more refined estimates of actual heights were available. At any

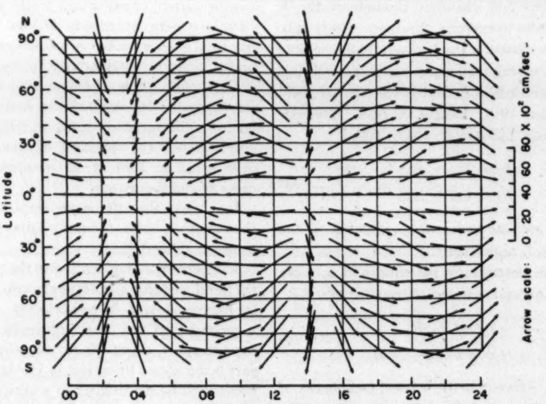

FIG. 1 – Distribution of the total wind velocity

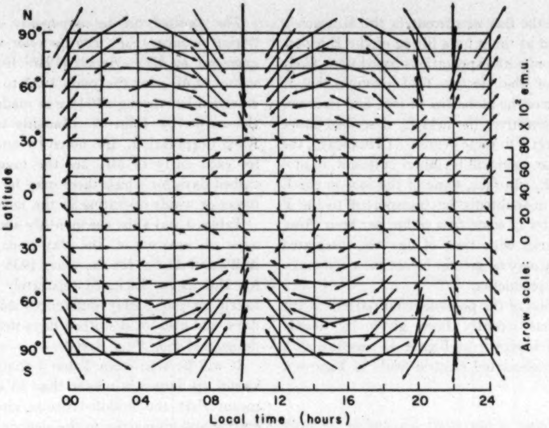

FIG. 2 – Distribution of the total electric field

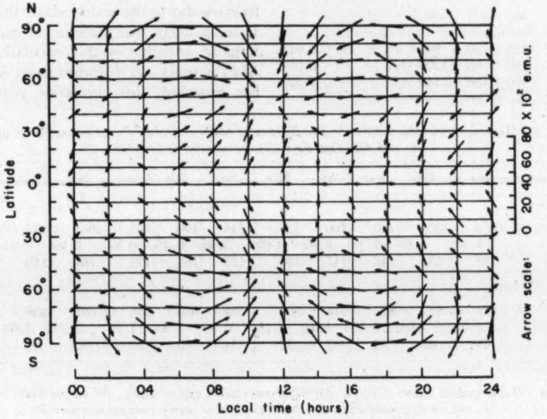

FIG. 3 – Distribution of the electrostatic field

rate it would appear that both the average wind speed and the electric conductivity increased from 1942 to 1948, the former by roughly about 50 pct, and the integrated conductivity by about 30 pct, the net effect providing an estimated increase in S_q amplitude roughly by the factor $1.3 \times 1.5 = 1.95$ at Huancayo from 1942 to 1948, if our assumptions are correct. F-region heating, however, may also increase Δh. As noted in Table 2 the average change from day to day in conductivity actually may be very small.

The total or integrated conductivity k, which appeared to increase with sunspot number, such that $k = 0.012 + 3.1 \times 10^{-5} R$, will probably be affected by the electrostatic field E_y. Appleton [*Appleton* and *Lyon*, 1957; *Appleton*, 1955] has shown that the flow of current in the E region is accompanied at times by a lifting of the E region, in good accord with expectations based upon likely directions of the electric field driving the S_q currents. Since the mobilities of ions and electrons are height sensitive, the field E_y described above will also affect k to some degree. At Huancayo, the E region near noon will be raised in height, in proportion to E_y. In fact, some of the ions in the E region will undoubtedly be transported to the F region at rates of some tens of km per hour. Also, since E_y varies with time of day the integrated conductivity may be greater before the noon maximum of ion production.

A derivation of the possible wind pattern in the E region has recently been given by *Maeda* [1955b] and is shown in Figure 1, together with the total or associated electric fields in Figures 2 and 3.

TABLE 2 – *Values of increments Δh_m and $\Delta h'$ in height in km, and calculated values E_y, A_S, and k in cgs units*

Year	R	Δh_m	$\Delta h'$	E_y	A_S	k

1940	67	150	90	1200	107	0.014
1948	141	190	150	1460	155	0.017

The observed average day-to-day change in the critical frequency f_0F_2 with the solar wave radiation expressed by δW_2—Bartels [1946] listed the daily values of δW_2 for the years 1922 to 1937, but an extended list through 1945 was made available to the writer by John W. Mauchly of Remington Rand Corporation. Also noted by notations p or P for each entry of δW_2 are the magnetically disturbed days for which there may be other electric forces or winds operating in the ionosphere.

Tables 3 and 4 list the monthly and yearly averages of squares of the day-to-day differences $\Delta\delta W_2$ and Δf_0F_2, for the years 1938–45, inclusive, for Huancayo. Included separately are averages taken for day-to-day differences $\Delta\delta W_2$ for quiet days, and also for disturbed days defined as those designated p or P by Bartels.

It will be seen from Table 3 that the monthly values are larger in winter than in summer. This means that the middle-latitude circulation generating and giving rise to the electric field directed west-east near noon above Huancayo varies more from one day to the next in winter than in summer. It seems likely that there is not much change in form or intensity of this circulation comparing Δf_0F_2 on quiet and disturbed days. As *Wulf* [1945] has remarked, this circulation pattern may be

one superposed upon a zonal circulation, which he also suggests may afford a means of explaining the 11h maximum in S_q.

The irregular features shown for $\Delta\delta W_2$ on disturbed days partially reflect other influences, such as additional electric fields [*Baker* and *Martyn*, 1953; *Martyn*, 1947].

Day-to-day changes in wind speed in various years of the sunspot cycle—It is well known that both the magnetic daily variation, upon which δW_2 is based, and f_0F_2, fluctuate more or less in unison with the sunspot cycle [*Chapman* and *Bartels*, 1940]. In fact, both δW_2 and f_0F_2 tend to increase with sunspot number, although we have noted above that increased positive values of the day-to-day differences in Δw_2 are on an average accompanied by larger negative differences Δf_0F_2.

It is also of interest to see whether or not the day-to-day variability of f_0F_2 and δW_2, as measured by the mean of the squares of day-to-day differences in these quantities, varies with the year of the sunspot cycle. Squares of Δf_0F_2 were derived for each of the years 1938–1945, inclusive. It will be seen from the Table 4 that there is little evidence of a substantial change in day-to-day differences in the values with sunspot numbers R for various years of the sunspot cycle. This is in accord with previous findings of *Chapman* and *Stagg* [1929, 1931], who showed that the variability was about the same in S_q at sunspot minimum at equatorial stations such as Batavia and Mauritius. It is interesting also to note that their results indicate that the daily variation in the north component of S_q shows larger day-to-day differences in amplitude in northern winter at both Batavia and Mauritius, as was noted here

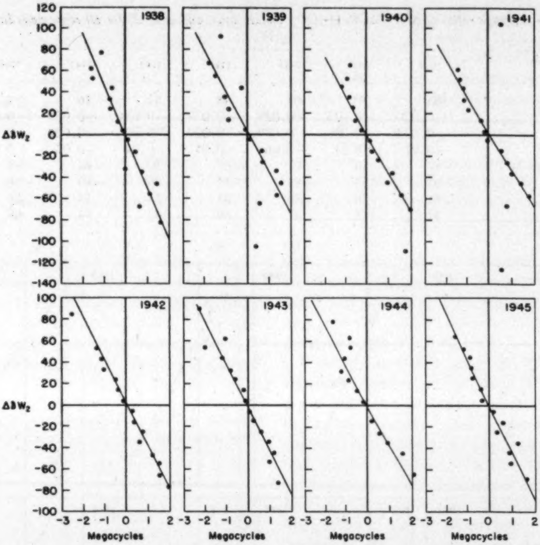

FIG. 5 – The day-to-day changes Δf_0F_2 with $\Delta\delta W_2$, Huancayo, all days, 1938–45

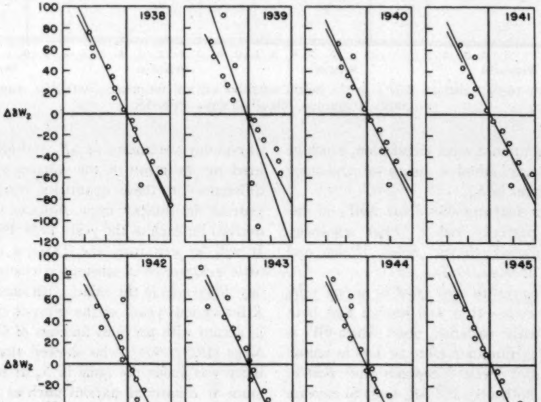

FIG. 6 – The day-to-day changes Δf_0F_2 with $\Delta\delta W_2$, Huancayo, quiet days, 1938–45

for Huancayo, also an equatorial station, reduced here for another series of years. Unfortunately, the day-to-day differences in f_0F_2 have not been available at these equatorial stations for the period of the present study.

The day-to-day magnetic and ionospheric effects interpreted in terms of the dynamo theory and winds near the 100-km level—The wind patterns at 60 to 100 km height with which we are concerned evidently can change considerably from one day to

the next, as indicated by the lifting action of electric fields upon the high ionosphere at height 200 km and higher. Table 5 lists the averaged daily ratios $\Delta f_0F_2/\Delta\delta W_2$ for the years 1938 to 1945 inclusive, both for disturbed days (labelled *p* or *P* by Bartels), and for the days not indicated as disturbed. Values of Δf_0F_2 were averaged for ten-unit intervals of $\Delta\delta W_2$, and graphed to obtain the ratios in Table 5.

The intersection of the two regression lines $y = a + bx$ where $y = \Delta\delta W_2$ and $x = \Delta f_0F_2$ are defined at each of the two points $x = 2.0$ Mc, and at -2.0 Mc, so that the high correlations r for E-region wind speeds and F-region height as measured by ion concentration is evident. It is apparent that other interdiurnal effects do not introduce major fluctuations, since the intersections of the regression lines at $x = \pm 2.0$ Mc are inclined at a small angle.

The yearly ratios $\Delta f_0F_2/\Delta\delta W_2$ are about the same for disturbed and for all days as shown by rows (1) and (2); values for disturbed days (1) are larger than for the quiet days (2) of 1943 and 1944 near sunspot minimum, and this difference is unexplained. These results are more fully illustrated in Figures 4 and 5. Figure 6 shows the corresponding results for quiet days, the regression lines being also indicated. Similar results by months are shown for quiet days (Fig. 7) and all other days (Fig. 8). In all of these figures a good linear interrelationship is clearly indicated.

Table 6 shows values averaged by months over the period 1938 to 1946, inclusive, the values in parentheses being adjusted for use of the seasonal values ω_1 given in Table 4 above. The values are largest in winter and least in the summer season, as was the case in Table 3.

Table 7 provides similar ratios for disturbed days, together with other particulars of interest.

Conclusions—Day-to-day changes in wind speed are probably the main cause of the day-to-day changes in S_q, because changes in S_q-amplitude correspond inversely to changes in f_0F_2. The dynamo electric field responsible for the magnetic diurnal variation is probably the result of a daily distortion of the existing zonal wind patterns. This electric field may lift or lower the E region slightly, as *Appleton* [1955; also *Appleton* and *Lyon*, 1957] has shown, thus affecting the integrated effective conductivity of the region carrying S_q currents; this change in effective conductivity is evidently small on the average, since the average f_0F_2 changes nearly linearly with the amplitude of S_q.

The day-to-day differences in wind speeds near the E region, as measured by effects measured at Huancayo, are greatest in northern winter and least in northern summer. This finding should be checked further, using results for other equatorial stations.

Water Gravity Waves Generated by a Moving Low Pressure Area

R. L. WIEGEL, C. M. SNYDER, AND J. E. WILLIAMS

Abstract—Hurricanes (typhoons) have an intense low pressure area which often moves rapidly over the surface of the ocean. The coupled water gravity waves generated by such a moving low pressure area have been studied in a towing tank. It was found that the waves generated in this manner had a phase velocity identical to the velocity of the moving low-pressure area. When the low-pressure area was moving at velocities less than the shallow-water wave velocity $\sqrt{gh}$, the waves were of nearly constant period. The period was that which when considered with the water depth would provide a wave phase velocity identical to velocity of the moving low-pressure area. As the group velocity of water gravity waves is less than the phase velocity the wave groups were formed behind the moving disturbance. If the low-pressure area is considered to be a gust it provides a mechanism for generating 'wind waves' of the period observed in the ocean if the forward speed of the gust is taken as the mean speed of the wind. When the velocity of the moving low-pressure area approached $\sqrt{gh}$ the characteristics of the waves changed (at $\sqrt{gh}$ phase and group velocities become identical in the linear theory). The wave disturbance consisted of a large wave followed by a few smaller waves. After the pressure area movement was stopped, the first wave would move ahead of the tail of the disturbance, the distance between the two phenomena increasing with increasing distance traveled by the waves. For certain combinations of initial conditions several waves were formed with this characteristic. These waves had the appearance of the records on the tide gages at certain locations of the East Coast of the United States during Hurricane Carol (and other hurricanes). A study of Hurricane Carol with respect to its speed of forward movement and the water depth over which it moved showed that it should have generated waves of the type obtained in the laboratory and which were actually recorded.

Introduction—A hurricane (typhoon) is a roughly circular tropical disturbance containing poor weather, heavy rains, an area of very low pressure, and strong counterclockwise (in the northern hemisphere) winds. The pressure in the center is often two to three inches (of mercury) lower than in the surrounding air. Maximum wind often exceeds 100 kn. The speed of advance of a hurricane varies considerably; however, the speed may exceed 30 kn in the more northern latitudes, as can be seen in Table 1 [*U. S. Weather Bureau*, 1957].

There is evidence [*Dunn*, 1951; *Unoki* and *Nakano*, 1955; *Harris*, 1956] that long water gravity waves are associated with some hurricanes. It was suggested by D. Lee Harris of the U. S. Weather Bureau that it might be possible to model the moving pressure area of a hurricane using a suction fan and a towing carriage. A preliminary test showed results which were interesting enough to warrant a more detailed study.

No attempt was made to model exactly the shape of the pressure pattern within a hurricane, nor to include the high winds and the associated wind waves; it was believed that these waves would mask the phenomenon being studied: the coupled wave.

A study of a similar type phenomenon had been made by *Press* and *Oliver* [1955]; they studied the flexural waves induced in a thin plate of aluminum by pressure pulses generated by a spark source. The experimental set-up was such that three phenomena could be studied: (1) the equivalent of a 'ground shot', that is, only flexural waves in the aluminum, (2) a combination ground wave in the aluminum and the wave induced by the air pressure wave traveling along the plate, and (3) only the air pulse-induced flexural wave in the aluminum plate. The last phenomenon was analogous to the study described herein. Press and Oliver found that the induced wave had a period such that the phase velocity associated with this period was the same as the velocity of the air pulse. It was found that the group of waves traveled with the group velocity associated with the measured wave period and that the group consisted primarily of waves of constant period rather than a dispersive group of the type associated with the ground blast waves.

Theory—*Kelvin* [1906] developed a theory for a diffused line pressure source moving over a body of infinitely deep water. *Havelock* [1909, 1922, 1926], working along similar lines, developed the theory for water of any depth, with the same assumptions being made as in the development of the linear theory.

Both Kelvin and Havelock found that the moving pressure source would generate transverse waves with phase velocities equal to the velocity of the moving pressure source. The wave periods would be the period associated with the particular wave velocity and water depth. The group of waves would form to the rear of the disturbance as the group velocity of water gravity waves is less than the phase velocity.

Havelock [1909] studied a diffused line pressure of the following sort

$$p = f(x) = \frac{P}{\pi} \frac{\alpha}{\alpha^2 + x^2}$$

where

$$P = \int_{-\infty}^{\infty} f(x)\, dx = \text{constant}$$

with x being measured in the direction of motion, p being the pressure and α expressing the degree of diffusion (it has the dimension of length, the 'width' of the pressure line and should be small compared with the normal wave dimensions). The amplitude of the waves formed by such a system is given by

$$a = \frac{C \cdot \dfrac{2\pi}{\lambda} P e^{-(2\pi\alpha/\lambda)}}{\left(1 - \dfrac{4\pi h/\lambda}{\sinh 4\pi h/\lambda}\right)}$$

where λ is wave length, h is water depth, and C is a constant (probably $2/\gamma$ where γ is the specific weight of water). The denominator expresses the effect of the difference between group velocity and phase velocity upon the accumulation of energy in the waves.

The relationship between the wave height (twice the wave amplitude a) and the wave velocity has been plotted in Figure 1 for a box two feet long traveling over water 1.06 ft in depth, taking α equal to one-half the length of the box which represents the 'hurricane' in our series of tests. On the same graph the experimental points of wave height versus velocity of the pressure area have been plotted. It is apparent that the solution, which depends upon linear wave theory, becomes invalid as the wave celerity approaches $\sqrt{gh}$ because the wave amplitude becomes very large, violating the assumption of the linear theory.

Havelock [1922] developed a more useful theory for a moving diffused pressure point which relates the wave resistance to the ratio of the wave celerity to $\sqrt{gl}$, where l is the radius of the pressure disturbance. Havelock's curves have been reproduced in Figure 2, and although they are not directly applicable to the diffused line source they do indicate the general relationship observed in our tests.

Experimental equipment—The experimental equipment consisted primarily of a suction fan mounted at the top center of a plywood box (bottom side open) mounted beneath a towing carriage on the wave-towing tank (Fig. 3). The box extended to within about an inch of the tank walls and to within about one inch of the water surface. Three box lengths were used: 2, 4, and 6 ft. Some data on the pressures within the boxes are shown in Figure 4.

A number of parallel wire resistance wave meters [*Wiegel*, 1956] were mounted on the structure. These meters were mounted as shown in Figure 5 for the tests in water depths of 1.06, 2.26, 3.08, and 4.07 ft. The meters were mounted in slightly different positions for the tests in water depths of 0.50 and 0.17 ft; in addition, wave meters were

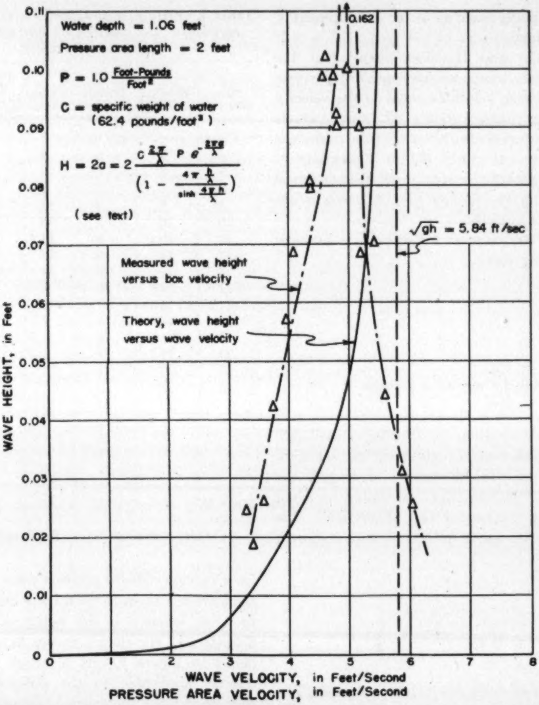

FIG. 1 – Comparison of measured wave height versus pressure area velocity, and theoretical wave height versus wave phase velocity

mounted at each end of the towing tank for the latter tests.

A flood light was installed within the box to light the water surface. A 35-mm Bell and Howell movie camera was installed in the camera pit (at about the center of the tank) to photograph the box and the water gravity waves as they passed the glass wall section of the tank. The camera operation was synchronized with the records from the wave meters by means of an event marker on the Brush penmotor which was used to record the output of the wave meters.

Laboratory procedure—The automatic carriage control unit was set for a chosen carriage speed and the motor was started. As soon as the carriage had come up to its steady speed the fan was started. The water-surface recorders were started prior to starting the fan so that a complete water-surface time history would be available. As the carriage moved past the camera pit, 35-mm moving pictures were taken. A sweep second-hand clock was in the field of vision of the cameras. The starting and stopping of the camera were recorded on the water-surface recorder chart by means of the event marker. When the carriage had run a sufficient distance the carriage and fan were stopped simultaneously. An electric braking system was used so that the carriage could be stopped within a distance of two or three feet. The recorders were left running until the wave system had reflected from the far end of the tank and passed the recording system.

Tests with all three boxes were made with water depths of 4.07, 3.08, 2.66, and 1.06 ft. In addition, tests with the 6-ft box were made with water depths of 0.50 and 0.17 ft.

Results and discussion—One series of tests was run with the fan turned on when the carriage was stationary. The only waves formed by the stationary low-pressure area and the associated 'winds' were of a very small amplitude and length; compared with the waves formed by the moving

FIG. 5 – Locations of wave meters on model hurricane for experiments in water depths of 1.06, 2.26, 3.08 and 4.07 ft

system they were considered to be 'noise.' The effect of starting and stopping the fan was unnoticeable. Another series of tests consisted of running the carriage without the fan operating. Records taken of the water surface again showed only 'noise.' From the two sets of tests it was evident that the waves discussed in this report were associated only with a moving low-pressure area.

Using the moving pictures taken of the experiments, together with the records of the wave recorders, it was possible to obtain the water-surface profiles under moving boxes. These profiles were not always constant with time; however, their general characteristics with respect to box velocity can be seen in Figure 6.

The main feature of the water gravity waves generated by the pressure area moving over the water surface was that the waves were essentially of constant period, except in very shallow water (Fig. 7). Thus the wave group did not resemble the group associated with an impulsive source. Figure 7 shows the wave trains after they have traveled about 200 ft from the point at which the moving pressure area had been stopped. The wave group was dispersive, as can be seen in the sample records in the right hand side of this figure. The group of waves, where there was a group, traveled with group velocity. As the group velocity is less than its phase velocity for gravity waves the group followed the low pressure area. The phenomenon was similar to that reported by *Press* and *Oliver* [1955].

In Figure 8 the measured wave periods have been plotted as a function of the ratio of the low-pressure area velocity $\sqrt{gh}$ and compared with the theoretical relationship between wave period and velocity for freely running waves. Except for relatively shallow water the period of the waves was such that the phase velocity was the same as the velocity of the moving low pressure area where the phase velocity is given by the set of equations

$$C = \frac{gT}{2\pi}\tanh\frac{2\pi h}{\lambda}$$

$$\lambda = CT$$

where C is phase velocity, g is acceleration of gravity, T is wave period, h is water depth, and λ is wave length computed from $\lambda = (gT^2/2\pi)$ $\tanh(2\pi h/\lambda)$. There was no apparent effect of the length of low-pressure area on the wave velocity.

One trend was evident. The smaller the water depth the greater was the value of $C/\sqrt{gh}$ for which measured values of the forced waves compared closely with theory. When considering relatively shallow water it appears that a forced wave moving with a given velocity has a smaller period than a freely running wave with the same velocity.

When the velocity of the moving low-pressure area was in the immediate vicinity of $\sqrt{gh}$ a different phenomenon was observed. The first wave in the series was of a 'solitary' (actually,

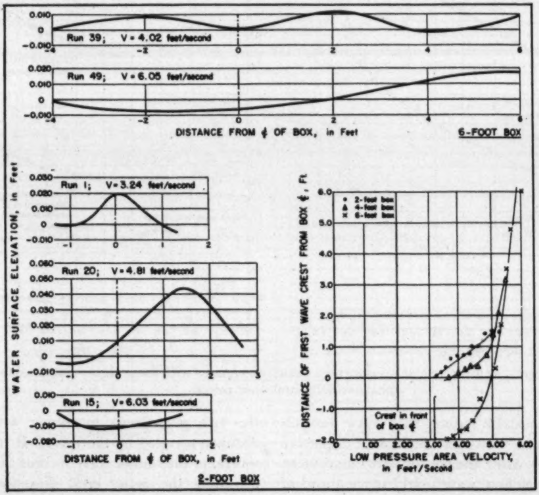

FIG. 6 – Relationships between water surface profiles generated by low-pressure area and velocity of low-pressure area

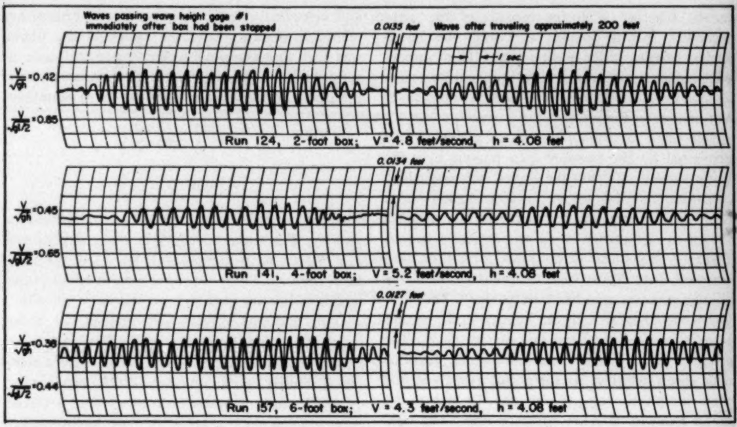

FIG. 7 – Sample records of waves generated by diffused low-pressure area moving with constant velocity over water

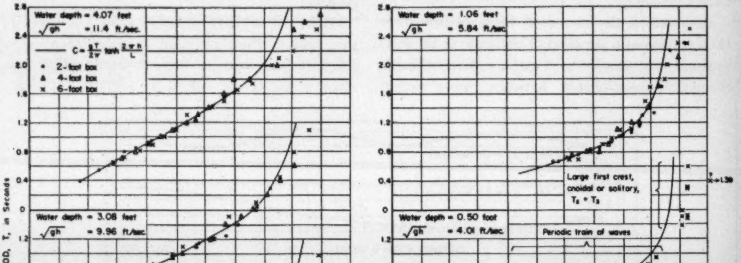

FIG. 8 – Wave period as a function of pressure area velocity compared with linear theory relationship between wave phase velocity and wave period

probably a 'cnoidal') nature; this wave was followed by a series of waves which were dispersive (Fig. 9 and 10). After the pressure area movement was stopped, the first wave would move ahead of the tail of the disturbance, the distance between the two phenomena increasing with increasing distance traveled by the waves. It can be seen in several of the sample wave records that the trough preceding the major crest disappears after the waves have traveled a ways. It appears that this

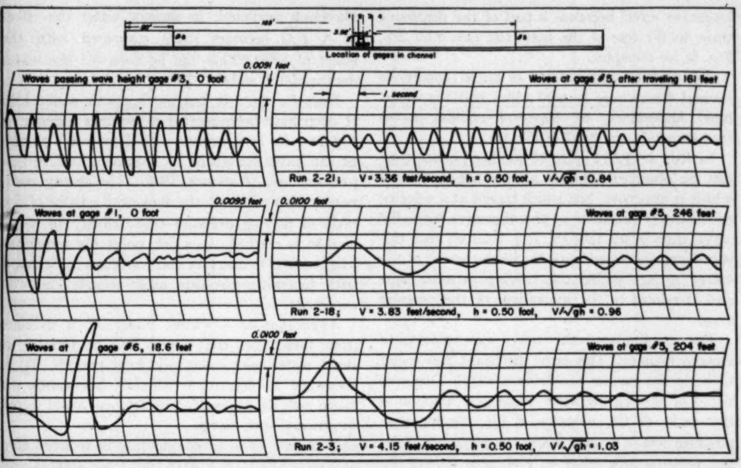

FIG. 9 – Surface-time histories of shallow-water waves generated by the 6-ft low-pressure area for a water depth of 0.50 ft

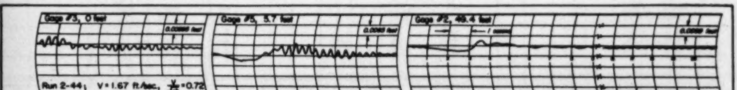

FIG. 10 – Surface-time histories of waves generated by the 6-ft low-pressure area for a water depth of 0.17 ft

'negative wave' becomes a part of the dispersive train to the rear of the first crest (see Run 2–3, Fig. 9, for example).

For certain combinations of initial conditions several waves were formed which had the superficial appearance, at least, of cnoidal waves (see Run 2–34 and 2–37 of Fig. 10).

In Run 2–44 of Figure 10 another phenomenon can be observed. This is a large negative wave which is dispersive, but which travels at a velocity considerably in excess of the dispersive 'periodic' wave train which follows. It is believed that this wave was associated with the displacement of the water surface under the moving pressure area and is related to the dimensions of the pressure area.

The amplitude of the waves were plotted in various manners. The most significant was found to be in the manner of *Havelock* [1922]. This consisted of plotting the wave height as a function of the ratio of the velocity of the moving low-pressure area to $\sqrt{gl/2}$ where l is the length of the low pressure area (that is, 2, 4, or 6 ft; Fig. 2). These data are shown in Figures 11 and 12. As Havelock predicted, in shallow water the effect of $\sqrt{gl/2}$ becomes small compared with the effect of $\sqrt{gh}$. This can be seen for the water depths of 0.50 and 0.17 ft for the 6-ft box.

Data for the 2-ft box moving over water 1.06 ft deep have been plotted in another manner in Figure 1 for comparisons with Havelock's theory of the waves generated by a moving diffuse line pressure area [*Havelock*, 1909]. The theory compares rather well with the data until a value of the ratio of moving pressure area velocity to $\sqrt{gh}$ of 0.86 is reached, at which point the measured height starts to decrease and continues to decrease with increasing pressure area velocity, as was expected.

Application to hurricane waves—It is evident from these tests that waves can be formed in shoal water with relatively long periods. It is necessary to determine whether hurricanes do move with the necessary velocity over shoal water to generate such waves.

In Figure 13 is a reproduction in reduced size of a section of U. S. C&GS Chart No. 1000 (Cape Sable to Cape Hatteras) showing water depths

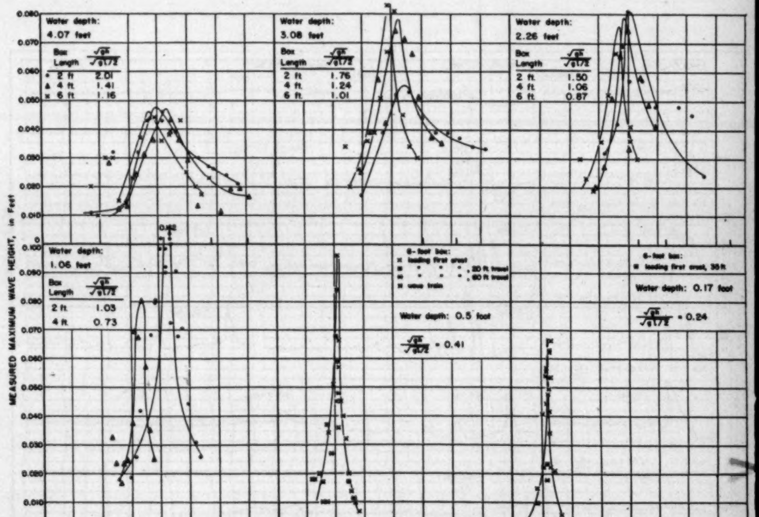

FIG. 11 – Relationship between wave height and $V/\sqrt{gl/2}$

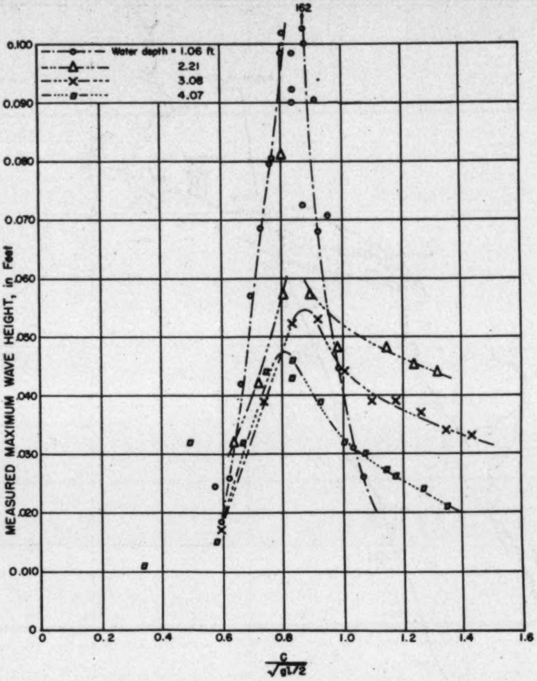

FIG. 12 – Wave height versus $C/\sqrt{gl/2}$ for the 2-ft box and various depths of water

off the East Coast of the U. S. The path of the center of Hurricane Carol is plotted on this chart. It travels over shallow water for an appreciable distance with a forward speed of approximately 30 to 35 kn (between Cape Hatteras and Long Island). The shallow-water wave velocities $\sqrt{gh}$ associated with water depths of 5, 10, 15, 20 and 25 fm are 18.4, 26.1, 31.9, 36.8, and 41.2 kn. It is evident that Carol should have been able to generate the type of long wave that would be known as a surge, especially in the vicinity of Long Island. This result is in agreement with the data presented by *Harris* [1956] which have been shown in Figure 14.

The forward speed of Carol was not usually great for the coastal area north of Cape Hatteras as can be seen from Table 1.

Application to wind-generated waves—The moving low-pressure area which was studied can be considered to be a part of a gust of low pressure in a wind blowing over the surface of deep water. The gust may last only for a minute or so at the air-sea boundary; however, it would be able to generate a train of waves with periods associated with the wave velocity identical to the forward velocity of the gust. Thus the mechanism assumed by *Eckart* [1953] has been shown to raise waves of the periods observed in the ocean. If, as Eckart assumes, the gusts on the average move with the mean wind speed this mechanism would explain the trend of increase of maximum wave period in a spectral analysis of a wave record with increasing wind speed as observed by *Barber* and *Ursell* [1948]. The fact that the speeds of such gusts (being large scale 'turbulence') have a

spectrum about the mean value would explain the spectrum of wave periods about a mean value. If the speed of advance of the low-pressure area is plotted as a function of the generated wave period in deep water one gets nearly the identical curve drawn by *Darbyshire* [1952] in his plot of observed maximum wave periods in the ocean versus maximum wind speed.

Conclusions—Water gravity waves, which were not edge waves nor wind waves, were generated by a low-pressure area moving over a water surface in a towing tank.

In the deeper water many of the characteristics, such as wave period, amplitude, and group velocity, could be predicted from a theory presented by *Havelock* [1909, 1922]. If one considers

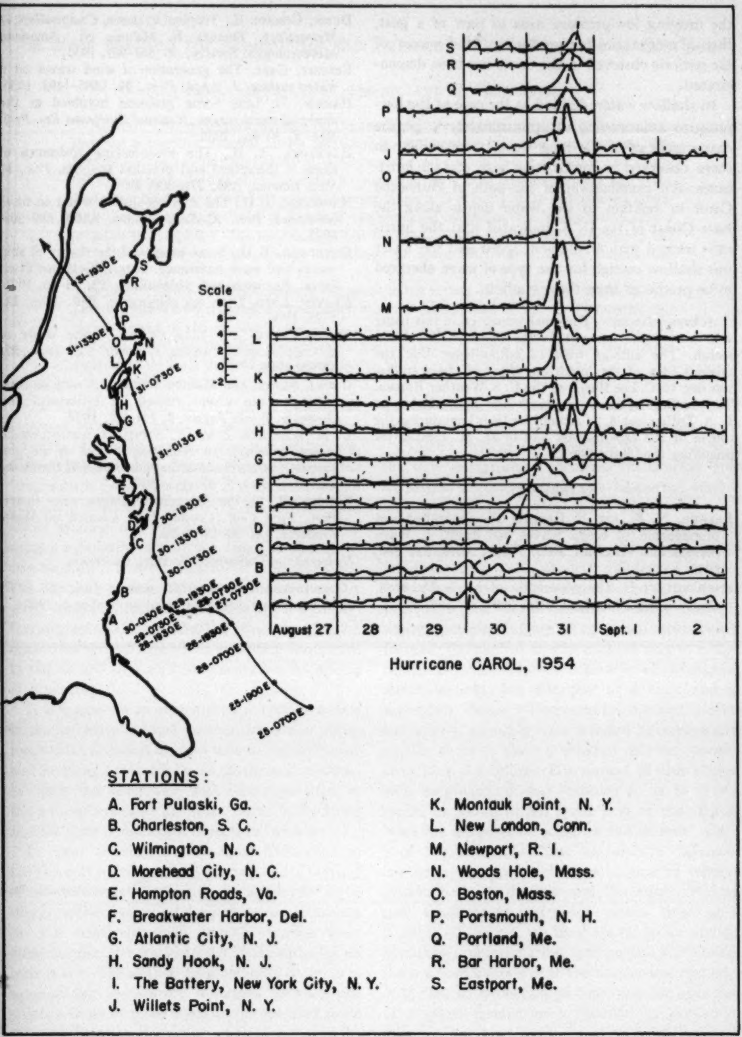

FIG. 14 – Hourly storm-surge height (observed minus predicted sea level), Atlantic coast tide stations, August 27–September 2, 1954 [after *Harris*, 1956]

the moving low-pressure area as part of a gust, then a mechanism for producing 'wind waves' of the periods observed in the ocean has been demonstrated.

In shallow water, defined as the case of the low-pressure area moving at approximately $\sqrt{gh}$, the characteristics of the long waves were similar to those observed in conjunction with certain hurricanes. An examination of the path of Hurricane Carol in relation to the water depth along the East Coast of the U. S. indicated that the hurricane moved with a sufficient speed and the water was shallow enough for the type of wave observed to be predicted from these studies.

Acknowledgments—The work presented in this paper was done under contract to the Office of Naval Research. The authors wish to acknowledge that the original idea of the hurricane phase of these studies was due to C. Lee Harris of the U. S. Weather Bureau. The authors wish to express their appreciation to R. A. Dilley and A. L. Arnold for their help during the course of the experiments, and to M. M. Lincoln for preparing the illustrations.

A New Method for Measuring the Thermal Microstructure of the Sea

R. J. URICK, L. C. PHARO, AND E. SKUDRZYK

Abstract—Previous measurements of the small-scale temperature structure of the sea have involved a sensitive thermal device carried through the water by a ship or submarine. The present method permits microthermal measurements to be made from a stationary or slowly drifting vessel by means of temperature elements held in a fixed position along a bar. Nine thermistor beads were spaced at varying distances along a 12-ft bar, and the temperature difference between successive pairs of elements was measured by means of a bridge circuit and a sensitive d c amplifier. The records obtained lead to a simple method for determining the correlation function of temperature describing the space distribution of the temperature changes.

A limited number of measurements was made in the waters off Key West, Florida, in conjunction with a field study of the fluctuation of sound transmission in the sea. The spatial and thermal scales of the microstructure are in rough agreement with the Kolmogorov theory of turbulence, and they lead to a prediction for the variability of sound transmission that agrees approximately with the field measurements.

During the past ten or 15 years a number of attempts have been made to obtain some understanding of the fine thermal structure of the sea. *Holter* [1944] at San Diego obtained expanded temperature profiles by using a sensitive thermopile, while *Urick* and *Searfoss* [1948] and *Lieberman* [1951] studied the horizontal microstructure by using a submarine to move a sensitive thermometer through the water. As a result of these studies it is now known that the sea possesses not only a gross thermal structure evidenced by the bathythermograph, but also, like the atmosphere, has a microstructure of dimensions extending downward in size as low as one's instrumentation is capable of measuring.

It is reasonable to attribute observed variations in the intensity of short underwater sound pulses received at distances up to a mile to the scattering and focusing produced by small thermal patches, in much the same way that inhomogeneities in the atmosphere cause air-borne sound to fluctuate and the light from distant objects to twinkle.

In order to relate the observed fluctuation to the thermal microstructure, we required a method of measurement that could be employed by a slowly drifting vessel, and which would give data on the relatively small patches having their greatest effect for wavelengths of the order of an inch or two. The method adopted, essentially, is to measure the temperature difference between two points a short distance apart in the sea, and to do this as a function of spacing so as to measure the thermal and spatial size of the microstructure. The water-borne device consists of a 12-ft bar, bearing thermistor beads at various intervals of separation between one inch and 128 inches.

Figure 1 includes a schematic of the bar, showing the nine temperature elements distributed over its length. In use, the bar was supported from a buoy to avoid the motion of the ship.

Although it is desirable to measure the water temperature at each of the thermistor beads simultaneously, or to observe differences in temperature between each element and a reference element at one end of the bar, simultaneously, it was not practicable from an equipment standpoint. Instead, the method finally adopted was to record the temperature differences between elements, not simultaneously, but one pair at a time and in succession. Figure 1 illustrates the method. Different pairs of elements were selected by means of a switch, so as to place a selected pair in opposite arms of a d c bridge. The output of the bridge, after amplification, was recorded so as to give a record as shown in the lower part of the figure. Note the temperature scale for this sample, which is of 15-sec duration. The temperature difference is observed to vary with time because of relative motion between the bar and the water. Having now temperature difference versus time as a function of spacing, we may appeal to an ergodic hypothesis concerning the temperature statistics of the sea, and assume that the fluctuation statistics of the sea as a function of time, and the statistics at a given instant as a function of horizontal distance, are equivalent. In other words, we will sample the sea by means of the drift of some one or two knots, and obtain the same result as if we

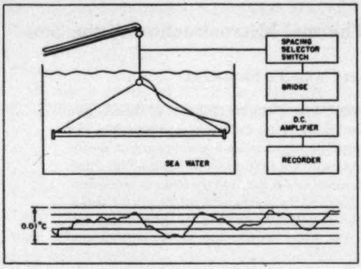

FIG. 1 – Block diagram of the recording equipment, showing a sample record of 15-sec duration

had sampled the sea through simultaneous measurement along the bar for a large number of locations.

Figure 2 is an example of 30-sec records obtained last summer off Key West, Florida, at a depth of 150 ft for the various separations between one and 128 inches. The temperature scale is such that the maximum deviation from the horizontal line on the lowest record is 0.02°C. Note that there is an increasing temperature deviation as the separation is increased. Measurements of this sort were made on several days at a number of depths down to 150 ft, during simultaneous measurements of sound transmission [*Whitmarsh*, *Skudrzyk*, and *Urick*, 1957]. No significant effect of depth was noted, either in the temperature microstructure out to a distance of 128 inches, or in transmission fluctuation. No noticeable difference could be observed between depths in the mixed layer and in the thermocline.

From records like these, temperature deviations were read off, and the mean-square temperature difference was computed and plotted against separation. Figure 3 shows some curves of mean-square temperature, drawn against separation in inches. The vertical scale corresponds to differences of a few thousandths of a degree Celsius. The cross is plotted at the average temperature difference and patch size found by *Urick* and *Searfoss* [1948] in these same waters at shallow depths. The straight line is a line having a slope according to the Kolmogorov theory of turbulence, [*Blokhintsev*, 1946, and *Batchelor*, 1953, chap. 6] which predicts, from dimensional considerations of the equilibrium energy distribution in isotropic homogeneous turbulence, a $\frac{2}{3}$-power law between the spatial and thermal scales of turbulence if the latter is measured in mean-square temperature units.

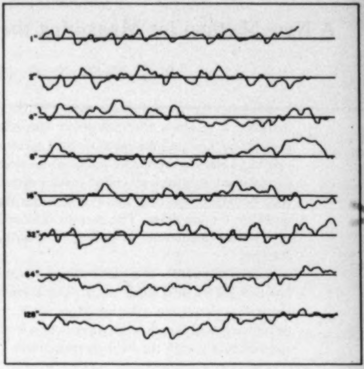

FIG. 2 – Examples of microthermal records showing the temperature difference over a 30-sec interval for various separations along the bar

In conclusion, a few words may be said about the relation between the microthermal data and the measurements made simultaneously on the fluctuation of transmitted sound in the ocean. To relate the two, and to predict the fluctuation from the observed microstructure, we require some sort of theory. A number of such theories are available [*Skudrzyk*, 1957], which all require that we express the microthermal statistics in terms of a temperature correlation function of the Gaussian type; that is, $R(\rho) = \overline{\Delta T(0) \cdot \Delta T(\rho)}/\overline{\Delta T^2} = e^{-a^2\rho^2}$, where $\Delta T(\rho)$ is the temperature deviation from the average at a point distant ρ from the origin at $\rho = 0$, and a is the 'patch size.' It can be shown that the mean square ΔT, except for a constant, is equal to one minus this correlation function, as shown on the left-hand side of Figure 3. However, if we try to represent the measurements by a Gaussian correlation function, we find ourselves in trouble in trying to get a decent fit; in fact, we find that we require more than one such function to agree with the measurements. This is shown by Figure 4, where the plotted circled points are the mean temperature differences as measured at the various spacings, and the dashed and the solid curves are the best that can be done on the basis of assuming one and two patch sizes, respectively. Some measurements of the vertical temperature distribution, obtained with the bar

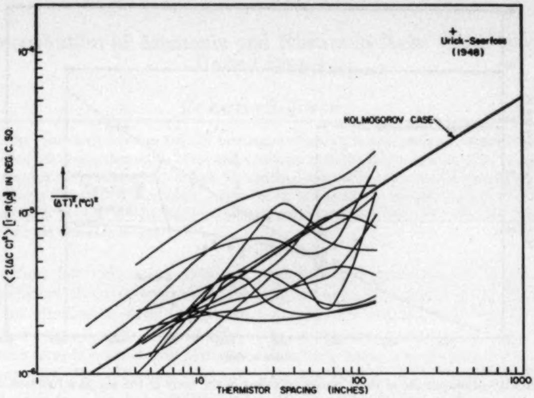

FIG. 3 – Mean-square temperature difference as a function of spacing as measured in different trials during several days

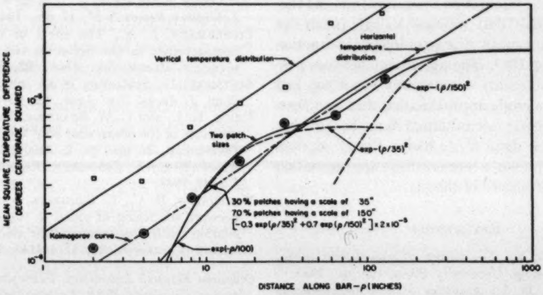

FIG. 4 – Temperature data with attempts to deduce the autocorrelation function of temperature assuming an exponential (exp ρ/a) or a Gaussian [exp $(\rho/a)^2$] correlation function; circled points are averages from the data of Figure 3 with the bar in a horizontal position; the squares show corresponding data points for the bar held vertically

held vertically, are indicated; although the slope is the same as that of the horizontal data, the mean-square temperature difference at the same separation is about three times as great, indicating a lenticular microstructure.

The measurements show that the root mean square temperature deviation increases constantly with the distance between the thermistors. This means that, in a strict sense, a correlation function does not exist. However, over a limited range, the Kolmogorov curve may be well approximated by a simple Gaussian correlation function or a superposition of two such functions corresponding to two different effective patch sizes. An approximation which does not do too badly is illustrated by Figure 5. What is plotted here is the standard deviation of the amplitude of successive transmitted acoustic pulses for different ranges between about 600 and 1400 yd. The crosses and circles show data for two frequencies. The focusing range here refers to the range inside of which focusing and defocusing is the dominant process by which the fluctuation occurs, and beyond which forward scattering of sound plays the dominant role. The

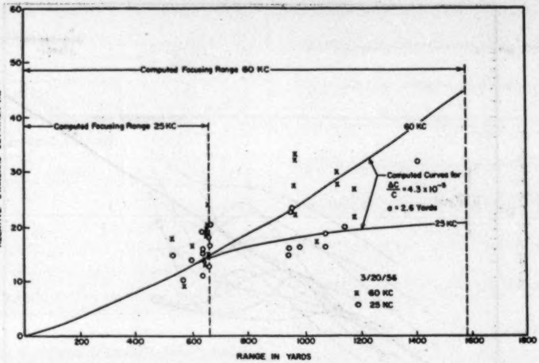

FIG. 5 – Variability of amplitude of short pulses traveling in the body of the sea as a function of distance; each point represents the standard deviation of groups of approximately 50 pulses at a particular range; solid curves show the predicted variability on the assumption of a patch size of 2.6 yards and mean index-of-refraction difference of 4.3×10^{-6}

curves show the fluctuation computed from the theory on the basis that we have a single patch size of 2.6 yd and a mean change of index of refraction $\overline{\Delta c}/c$ of 4.3×10^{-6}. The agreement between prediction and observation apparently is not too bad in spite of the crude approximation that had been made to the basic microthermal data. Presumably more could be done if we had a theory of fluctuation based upon a more realistic approximation to the microstructure of the sea.

The Distribution of Ammonia and Nitrate in Rain Water over the United States

CHRISTIAN E. JUNGE

Abstract—Quarterly average maps of ammonia and nitrate concentration in rain water over the United States are discussed. These maps indicate that the major sources for both components are near the ground and over land. Comparison with soil maps makes it very likely that the ammonia distribution is primarily controlled by the acidity of the soil. In case of nitrate, no correlation to other geographical parameters could be found, but again, the soil appears to be the most probable source.

Introduction—From July 1955 to July 1956, rain water was collected at about 60 stations in the United States for chemical analysis [*Junge* and *Gustafson*, 1956]. In the specially designed collectors the rain water came in contact with plexiglass and polyethylene only. The collectors were only exposed during rainfall. This was necessary to avoid the influence of dry fallout between the rains which would increase the concentrations in an uncontrolled manner, especially in the dry southwestern areas. The disadvantage of this procedure is that the observers may miss some rain. Because of the randomness, this, however, is likely to have very little influence on the average values.

The samples of each month and station are batched prior to analysis in order to obtain monthly average values. Small amounts of toluene in the sampling bottles protected the samples against activity of micro-organisms. The determination of NH_4 was done colorimetrically by Nessler's reagent, after it was transferred to distilled water by microdistillation to avoid interference with other ions. The determination of NO_3 was also done colorimetrically by adding a chloroform solution of brucine alkaloid and sulfuric acid to the sample. For further details on the network and the sampling procedure, see *Junge* and *Gustafson* [1956 and 1957].

General remarks about the interpretation of rain-water analysis data—The monthly data were currently plotted on maps and checked with respect to the consistency of the concentration pattern. The analysis of apparently inconsistent values was carefully repeated. A few values were considerably higher than the surrounding ones. They were regarded as being contaminated, either by local air pollution or after collection and excluded from further consideration.

It soon became apparent that the monthly concentration maps showed a consistency of certain general features on which fluctuations caused by weather were superimposed. We did not succeed in finding any correlation of the fluctuations with the monthly weather, but it appeared worthwhile to study the consistent pattern by preparing quarterly maps, representing the average concentration weighed with respect to the amount of rainfall. These maps are reproduced in Figures 1 to 8 and will be discussed briefly in this paper.

In a number of samples the NH_4 concentration was below the limit of detection, which was 0.02 mg/liter. In order to obtain the most realistic average data, a concentration of 0.01 mg/l was assigned to these samples. A value of 0.01 mg/l on the NH_4 maps indicates, therefore, that no NH_4 was found during the whole period.

Because of the complexity of rain-water chemistry, the interpretation of these quarterly maps is not easy. To begin with, very little is known about the form in which the compounds enter the rain water; that is, as particulate matter or as gas. Both forms are almost always present. From the few data available [*Junge*, 1956] it appears that the concentration of the gases, NH_3 and NO_2, possibly also some NO, which can form NH_4^+ and NO_3^- in rain water, is considerably higher than the concentration of the corresponding ions NH_4^+ and NO_3^- in the aerosols. The small amount of NO_2^- present in rain water is included in our NO_3^- values. The importance of the gas traces for rain chemistry may, therefore, be much greater than hitherto considered. On the other hand, estimations indicate that the removal of particulate matter by rain may be more efficient. As a very tentative approximation, we can assume that these two facts compensate each other and that gaseous and particulate matter contribute to the rain water content in about equal, but probably varying parts.

Another question is, where the major part of the material is picked up, within the clouds by the cloud droplets, or below the clouds by the falling

raindrops. An estimation of the air volumes involved shows that the first process is the predominant one, if the component is uniformly distributed throughout the troposphere. If the component is, however, concentrated in the layers near the ground, the second process may become more important [*Junge* and *Gustafson*, 1957].

For the interpretation of the pattern on Figures 1 to 8 the following consideration may be helpful: If we assume a component to be uniformly (vertically and horizontally) distributed throughout the troposphere, it is fairly obvious that this should also be true for its concentration in rain water as far as average values over fairly long periods are concerned. There may be higher values in the northern latitudes by a factor of two or so, because of the lower liquid water content of raining clouds as compared with more southern latitudes. But these differences in cloud climatology can only result in very gradual changes over large distances. This theorem of approximately uniform distribution in air and rain could be confirmed in the case of two other components, chloride and strontium 90. Since the ocean is the predominant source of chloride it becomes, on the average, uniformly mixed over the inner part of large continents, resulting in a very uniform distribution of its average concentration in rain water [*Junge* and *Gustafson*, 1957]. Most of the Sr^{90} is stored and accumulated in the stratosphere (probably over years) and constantly released to the troposphere where it is washed out by rain. Sr^{90} can therefore be assumed to have fairly uniform distribution, at least along the same latitude (there is some indication that the transport through the tropopause depends on the latitude) in correspondence with fairly constant Sr^{90} concentrations in rain water (between test periods) within the same latitude range [*Collins* and *Hallden*, 1957].

A look at the maps reveals that the NH_4 and NO_3 concentrations in rain water are far from being uniformly distributed. In general, the values drop near the coast and are low over the ocean, as indicated by the data from the Bermudas, the Azores, and some weatherships (the latter two not indicated in the maps). It further appears that certain geographical areas over the United States show, throughout large parts of the year, consistently low or high concentrations. If we apply the theorem of uniform distribution in air and rain water in a reversed way, it must be concluded that the major sources of fixed nitrogen are not over the

ocean, but bound to certain geographical areas over land. This implies that they are very likely to be at or near the ground.

The distribution pattern of NO_3 in rain water excludes the photochemical production of NO_2 in the stratosphere as a possible supply for tropospheric nitrate, as sometimes speculated [*Virtanen*, 1952]. It is also obvious that there is no correlation to thunderstorm activity. This confirms estimations by *Hutchinson* [1954] and others, for example, [*Virtanen*, 1952] that NO_3 formed by lightning can only account for 10 to 20 pct of the observed NO_3 concentrations in rain.

The NH_4 maps—The NH_4 maps, Figures 1 to 4, show the following more or less consistent features:

Maxima tend to appear over (a) California, particularly in the early summer (Fig. 4) where it is confirmed by three exceptionally high values; (b) the Pacific Northwest; (c) New Mexico and northwest Texas; (d) the North Central States (this maximum is very broad and fluctuating); (e) the Northeast (this maximum is weak and not regular, and often part of (d)); and (f) Florida, except in Figure 2 (this maximum is often indicated by one value only and is very weak).

Minima can be distinguished over (g) the whole Southeast (in this area, with the exception of Florida, almost no values reach the limit of detection; this minimum is a regular feature on all monthly maps; in Fig. 2 this minimum does not show up clearly because of the overall low NH_4 level during this period); and (h) the northern Rocky Mountain area, extending farther south in winter.

The comparison with a large variety of maps of geographical parameters, such as density of industry, population, and agricultural activities, did not produce evidence to explain the NH_4 distribution pattern. Finally, the soil maps provided a clue for an understanding. The Southeast is characterized by the yellow reddish laterite soil which is depleted of its alkali content and has a low pH value. Soils of low pH absorb whatever NH_3 may be formed by decomposition of organic material or added by fertilizer. The contours which separate the soils of low pH in the Southeast run closely parallel to the drop of the NH_4 concentration in this area. This decrease in the NH_4 concentration is quite pronounced, often by a factor of ⅛ to ¹⁄₁₀ over a distance of 500 miles.

The exhaustion of NH_3 from soils has been studied in detail [see, for example, *Harmsen* and *Van Schrever*, 1955, and *Allison*, 1955] and depends on the supply of NH_3 on the one hand, and on the pH, structure, and humidity of the soil on the other. The latter two items vary considerably with locality and time, so that the first two will control the exhaustion of NH_3 in a more general way. In areas with low soil pH, as in the Southeast, the supply of NH_3 is of little importance, since all NH_3 is retained in the soil. Loss of NH_3 from soil starts at $pH = 6$, with no observable escape below this value. In areas of alkali soils, as in the West and North, the production of NH_3 becomes the controlling factor.

It is hard to estimate this production. Part of it is certainly caused by agricultural activities and will be related to the consumption of ammonia-containing fertilizers. A considerable fraction of these fertilizers is applied as liquid NH_3, injected into the soil or into irrigation ditches, five per cent of which are estimated to evaporate directly into the air. By far the highest amount of these liquid fertilizers is used in California in spring and this may, at least in part, account for maximum (a) [*Scholl*, *Wallace*, and *Fox*, 1955]. It may be mentioned in this connection that California has seven ammonia plants, Texas four, and Utah one.

The maxima (b) through (e) are probably caused by agricultural activities in combination with high soil pH. Maximum (e) may, to some extent, be influenced by industry and denser population, but the share of these human activities is obviously not of great importance. In the southeast of Florida, coral rock is dominant which may be responsible for maximum (f) because of a higher soil pH.

The question immediately arises as to why the NH_4 concentration in rain water can drop so rapidly and to such an extent along the borderline of the acid laterite soils. A drop by a factor of two could be accounted for by the higher amount of rainfall and liquid water content in raining clouds in the Southeast, especially in summertime, resulting in a higher dilution of a given amount of the constituents. But the NH_4 drops (with the exception of Fig. 2) by a factor of $\frac{1}{5}$ to $\frac{1}{10}$ and this can only be caused either by a very short life-time of NH_3 in the air or by a rapid decrease in concentration of NH_3 in the ground layers as a result of vertical mixing with higher tropospheric layers. The second effect can be illustrated by a similar situation in the case of the chloride distribution.

FIG. 8 – NO_3 concentration mg/l; average April–June 1957

The sources of chloride are the sea-spray particles formed over the ocean. It was shown [*Junge* and *Gustafson*, 1957] that over the oceans and near the coast the majority of sea-spray particles are concentrated in the layers near the surface and are washed out primarily by the falling raindrops below the clouds. As the air masses move inland, the particle concentration in the lower layers where most of the rain is formed is rapidly decreasing by vertical tropospherical mixing. This can result in a decrease of Cl in rain water by a factor of ⅕ to 1/10 over a distance of about 500 miles in agreement with the observations. The estimated decrease of sea spray particles by washout over the same distance is, on the other hand, too small to account for the observed values.

The NH_4 drop towards the southeast across the borderline of acid soils shows similar features as that of Cl along the coasts. The NH_4 values decrease also by a factor of ⅕ to 1/10 over a distance of about 500 miles. It appears reasonable, therefore, to conclude that vertical mixing again is the predominant process. It can be assumed that NH_3 is concentrated in the lowest tropospheric layers over the source areas farther north and west just as the sea spray over the oceans. It may well be that a rapid washout of the NH_3 by rain supports the dilution effect of mixing, but at the present time nothing is known about the lifetime of ammonia in the air.

The maps indicate a seasonal variation of the general NH_3 level with a maximum in late spring and early summer and a minimum in the late fall and early winter.

Discussion of NO_3 maps—The fluctuation in the concentration pattern with the monthly maps of NO_3 concentration, Figures 5 to 8, was more pronounced than with NH_4 and most other chemical constituents. The following features on the quarterly maps seem to have some reality. Maxima tend to appear over (a) the northern part of the United States, often split by the Great Lakes area; (b) the western Texas area, except in Figure 5; and (c) California, and adjacent areas eastwards on some of the maps. Minima tend to appear over (d) the northern Rocky Mountain area; and (e) the Southeast.

In general, some of these features have a similarity with the NH_4 maps, although details do not agree. The minimum in the Southeast is less regular and the difference in concentration against the adjacent area in the West and North is smaller than with NH_4. We think that this NO_3 minimum is largely the result of dilution by the higher rates of rainfall and liquid water content of the clouds in that area. Maximum (c) may be caused by smog in the Los Angeles Basin, which primarily occurs during the late summer and fall and is known for high NO_2 concentrations. Maximum (a), especially the part east of the Great Lakes, may be caused by industrial activities, but the part west of the Lakes can only be explained by some soil activity, either natural or agricultural. Maximum (a) is strong during the winter. Stagnation of stable air masses in this season may enable a higher accumulation of the NO_2 in the lowest tropospheric layers or provide a longer time for the formation of the NO_3. The impression that a time delay for the formation of NO_2 in the air may be involved is gained by the observation that the monthly pattern of NO_3 does vary much more and is thus bound to a lesser degree to geographical areas than most other components.

As already indicated, the NO_3 maps exclude as possible major sources the lightning and photochemical formation in and diffusion downward from the stratosphere. Furthermore, the major amount of NO_3 in rain water can not come from industrial or other human activities because in this case a much closer relationship to industrial areas in the Northeast and elsewhere should be expected. The maps rather point to the earth surface as source. These two possibilities exist:

(1) the NO_2 is formed by oxidation of NH_3. This would explain some similarity with the NH_3 pattern, blurred by a delay due to reaction time.

(2) Along with the considerable amount of N_2O, which is well known to be produced and released by the soil [*Goody* and *Walshaw*, 1953], a small fraction of NO or NO_2 may be formed directly in the soil. According to *Allison* [1955], NO is formed from HNO_2 in acid soils (PH $\leq$ 5), but this does not seem to agree with the soil maps.

We may summarize this discussion on NO_3 in rain water by saying that its formation appears primarily to be bound to the soil, although some industrial sources are likely. More detailed conclusions have to wait for further investigations.

Experimental Studies on the Relation between Transpiration Rate and Meteorological Elements

YOSHITO YAMAOKA

Abstract—Water loss caused by transpiration is significant, especially on a bright summer day. The utilization of precipitation as a water resource will be affected largely by transpiration. Thereupon, the investigation of the transpiration rate was carried out as a fundamental datum of water resources, using a wind tunnel which can maintain any meteorological condition. Various examinations on the potometer method were performed and the method was found satisfactory in our investigations. The transpiration rate obtained by the potometer agreed within ±2.4 pct with that of the potted plant. The following empirical formulas were obtained from the relation of the transpiration rate to radiation intensity and wind velocity for *Myrica rubra*.

$$T = T_0 \mp v/(0.55 \times 10^{-1.87R} \cdot v + 0.32 \times 10^{-2.35R})$$
$$T_0 = (2.09R + 1.67)\, H_d + 35.62R$$

Also, the relations of the leaf temperature to transpiration rate and meteorological elements were studied. Some systematic relations were found.

Introduction—It has already been reported by many investigators, such as *Briggs* and *Shantz* [1916], *Cribbs* [1919, 1921], *Blaydes* [1928], *Meyer* [1932], *Kadota* [1950], *Shapiro* and *DeForest* [1932], and others, that the transpiration rate shows a daily periodicity, and its correlation with meteorological elements has been investigated.

Meyer [1928], *Thornthwaite* and *Holzman* [1942], *Thornthwaite* [1943], and others, have investigated the effect of air temperature on transpiration rate. The trends were represented by linear relations. The gradually accelerating tendency of transpiration rate with increase of air temperature can be seen in the results of laboratory experiment by *Roeser* [1932].

Martin [1943], *Bialoglowski* [1936], and others, have shown the linear relation between transpiration rate and relative humidity.

Martin [1935] investigated the effect of radiation intensity on transpiration rate of *Helianthus annuus* under natural conditions, using shade tents, and found the relation to be linear within the limits of experimental error. As to the effect of wave length of light, *Leclerc du Sablon* [1913] suggested that the accelerating effect of radiation on transpiration rate may be caused partly to heating of the leaves and partly to a change in the permeability of the protoplasm. *Iwanov* and *Thielmann* [1923] have shown that the transpiration rate under blue-violet light is 50 or 60 pct more than that under red-yellow light of the same intensity. *Lepeschkin* [1930] has shown that the permeability of the protoplasm of *Elodea* leaves increases under methylene blue light with increase of the light up to ten per cent of full sunlight, but beyond this intensity the change in the permeability of protoplasm is very little.

Renner [1910], *Seybold* [1929ab, 1930], *Wrenger* [1935], *Wilson* and *Livingston* [1937], *Nakayama* and *Kadota* [1948–9], *Satoo* [1948abcd, 1949ab, 1952, 1953], and others, have investigated the effect of wind velocity on transpiration rate. According to Renner, this effect on *Rhododendron hybridum* was indistinct under the scattered light. Seybold reported that the effect on plants mainly composed of cuticular transpiration was increased by the wind, but on plants mainly composed of stomatal transpiration was small. According to Wrenger's experiments on 38 species in a laboratory, the transpiration rates were raised to their maxima for the species (12 to 150 pct) after 10 or 15 minutes, and then gradually decreased. Nakayama and Kadota reported that the transpiration rate of the Japanese pine decreases or increases by the influence of wind according to clear or cloudy weather, respectively. The lag period of transpiration rate caused by the change of wind velocity was measured on willows by Wilson and Livingston, and on *Cryptomeria japonica* by Satoo.

As noted above, there are many reports on the effects of meteorological elements on transpiration rate. Since these studies were not satisfactory to our present aim, the following experiments were carried out.

Examination of the method for measuring the *transpiration rate*—Various methods have been used to measure the transpiration, such as *Stahl's* [1894] or *Bakke's* [1914] cobalt paper method, the *gasometrische Methode* employed by *Schratz* [1931], and *Minckler* [1936], the weighing method, the potometer method, and others. The weighing method may be one of the most useful for this purpose. Using potted plants, it becomes necessary to expose the plants under constant environmental conditions for a long period in order to take readings, because of the rapid decrease of the sensitivity of balance according to the unavoidable soil weight in the pot, as has already been mentioned by *Stocker* [1929]. Using cut shoots instead of potted plants eliminates the need for the weighing method. From this point of view, the author has adopted the potometer method throughout the investigation, except the weighing method has been employed in comparing the transpiration rates of potted plants with shoots.

Strictly speaking, the potometer method does not give the true transpiring rate, but rather the amount of water absorbed by the cut end of the shoot. Nevertheless, according to *Knight* [1917, 1922], the amount of water absorbed by the cut end almost exactly coincides with the amount of water transpired; wilting will occur with only one per cent decrease of water content in a leaf.

Another difficult problem is the effect of detaching a branch from its parent tree. The theories and experimental results on this problem differ widely in the investigations by *Iwanoff* [1928], *Darwin* and *Pertz* [1911], *Laidlaw* and *Knight* [1916], *Knight* [1922], *Stålfelt* [1929abc, 1932], *Firbas* [1931], *Kamp* [1930], *Schratz* [1931], *Huber* [1927], *Stocker* [1929], *Pisek* and *Cartellieri* [1931, 1932, 1939], *Bosian* [1933], *Kadota* [1950], *Pfleiderer* [1933], and others. It was necessary to examine this problem before carrying out our investigation.

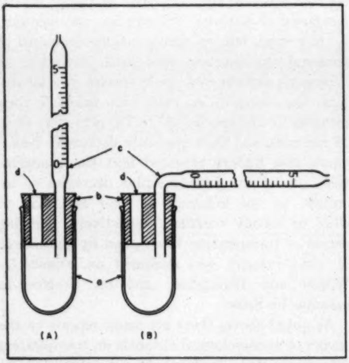

FIG. 1 – Diagram of the potometers used; A, vertical measuring pipette type; B, horizontal measuring pipette type; a, test-tubes; b, rubber stoppers; c, measuring pipettes; d, hole for shoot

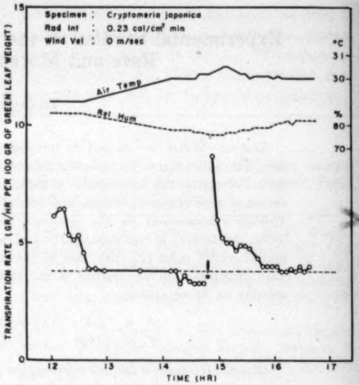

FIG. 2 – Transpiration rate before and after the severance of stem; ! shows the instant of severance; Aug. 13, 1953

Apparatus used—Two types of potometers (Fig. 1) were employed. Figure 1A shows the vertical measuring pipette type potometer, in which the pressure of water column from 8 to 25 cm will be exerted upon the cut end of a shoot. Figure 1B shows the horizontal measuring pipette type potometer, in which nearly constant water pressure is maintained. A potometer is supported by a metal stand.

Comparison of the transpiration rate of shoots with rooted plants—Six *Cryptomeria japonica* two years old and five *Cinnamomum camphora* three years old had been prepared and placed in pots by Miyano nursery in November 1952. Two of the *Cryptomeria japonica* and one of the *Cinnamomum camphora* and two *Diospyros kaki* grown in pots for about one year after planting in 1950, were selected for our purpose. The experiments were carried out in August and September, 1953.

In the experiment, the plotted plant was put in the laboratory the day before in order to allow the soil temperature to approach the room tem-

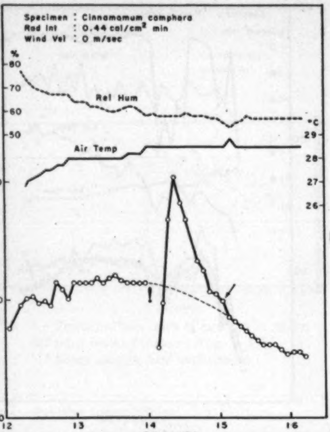

FIG. 3 – Transpiration rate before and after the severance of stem; ! shows the instant of severance; Sep. 18, 1953

perature which was kept as nearly constant as possible. Then, the pot was made water tight and was hung on a precision balance. The sensitivity of the balance was adjusted to ±5 mg. The experiment was carried out under the radiation of eight electric lamps of 500 watts each. Weighing of the potted plant was continued until the transpiration rate became constant. After attaining the constant value, the stem of plant was severed a few centimeters above its base and the fresh surface was quickly cut a second time under water again in order to exclude the air from its water-conducting system. The shoot was mounted in a potometer, was put carefully in place and reading was continued. In order to take into account the rate of water loss from the pot in the value of transpiration rate, the pot was weighed a number of times after applying vaseline to the cut surface of the stem. The rate of water loss from the pot was almost negligible when compared with the transpiration rate. Experimental results thus obtained with respect to one of each of the three species were shown in Figures 2 to 4. In every figure the exclamation mark (!) shows the instant of severance of the stem.

The transpiration rate after cutting is sometimes much higher or much lower than the value before cutting, and in some cases is almost equal to the value before cutting. After one or two hours the transpiration rate approaches the value before cutting within ±2.4 pct, except in case of *Cinnamomum camphora*, where wilting was observed only one hour after the cut as shown by the arrow in Figure 3. From these examinations, it is considered that a shoot mounted in a potometer will serve satisfactorily in our investigation, one or two hours after the cut, and wilting has not occurred.

Observation of stomata—The author observed the behavior of stomata of *Ilex rotunda Thunbergii*, using Suzuki's Universal Micro Printing (SUMP) method [*Kawakura*, 1931]. There are several methods for observing stomatal openings, such as *Stahl's* [1894] cobalt chloride method, *Darwin's* [1898] horn hygroscope method, *Lloyd's* [1908] alcohol method, *Darwin* and *Pertz's* [1911] porometer method [see also *Knight*, 1916], *Lloyd's* [1913] microscope method, infiltration methods [*Molisch*, 1912; *Monji*, 1938; *Stålfelt*, 1929b], and others. But the SUMP method was adopted because the permanent pattern of stomata can be taken in a short time by merely pressing a SUMP plate against the back of a leaf, and the pattern can be examined under a microscope. Care should be taken that a small portion of a leaf once patterned should not be used again to pattern the next SUMP plate, because the tissue of a leaf may be injured by the solvent of the first plate.

in the open are shown in Figure 5. Air temperature, relative humidity, radiation intensity, and wind velocity during the observation were, 25.0–23.7°C, 54–57 pct, 0.89 cal/cm²min, and 0.3–1.0 m/sec, respectively.

We can see from these three photographs that the stomatal openings of the shoot without water supply were almost completely closed 85 minutes after the severance, but were wide open in case of the shoot with water supply. The commencement of wilting of leaves on the shoot without water was observed visually 35 minutes after the severance. The leaves of the shoot with water remained unwilted throughout our observation. From these observations, we can likewise say that a shoot mounted in a potometer can serve satisfactorily in our investigation if wilting does not occur.

TABLE 1 – *Various constants of shoots*

C	0.55	46	548	215	0.39	39.3	
D	0.50	151	1048	445	0.42	38.9	

Cutting process of a branch—The cutting process of a branch must be examined in order to find out the most convenient and effective way to treat the shoot of various species under investigation. Five species, *Myrica rubra*, *Robinia pseudacacia*, *Podocarpus macrophyllus*, *Pinus Thunbergii*, and *Cryptomeria japonica*, were selected among; (1) the broad-leaved evergreens, (2) the broad-leaved deciduous trees, (3) the acerose trees. The march of transpiration rate of shoots treated in three ways, (1) cut under water, (2) cut under water after the cut in air, (3) cut in air, were compared under the same environmental conditions.

Figures 6 and 7 show the experimental results. Curves A, B, C, and D, show the march of transpiration rate of cut shoots treated in different processes: A, cut under water; B, cut under water one second after the cut in air; C and D, mounted in a potometer one and five seconds respectively after the cut in air.

In case of *Myrica rubra*, every shoot remained in healthy state for at least 2 or 2½ hours. It is easy to maintain a cut shoot for five hours or more in a healthy state.

In case of *Robinia pseudacacia*, only one cut shoot remained healthy at least for 1.5 hours, and three started to wilt at the instants shown by the arrows in Figure 7. Furthermore, it was found that the shoots of this species are very difficult to

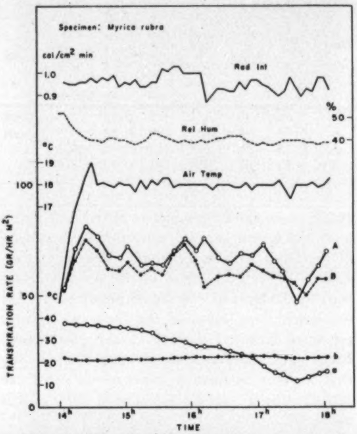

FIG. 10 – Transpiration rate of cut shoot under decreasing water temperature in potometer and that of under nearly constant water temperature; Feb. 4, 1952, laboratory experiment; curves a and b show the water temperature of A and B, respectively

maintain in healthy state more than an hour in full sunlight even when cut under water.

In case of *Podocarpus macrophyllus* and *Cryptomeria japonica*, three shoots out of four remained in a healthy state at least for two hours. In case of *Pinus Thunbergii*, two shoots out of four remained in a healthy state at least for three hours. Thus, the effect of cutting process on transpiration rate differs widely with different species. From this point of view, it is necessary to examine in advance the most appropriate cutting process with respect to the species to be investigated.

The effect of change of water pressure—This effect was studied using two types of potometer previously mentioned. Two shoots were mounted in the potometers separately, and the transpiration rate trends were compared in the open under the solar radiation through fleecy cloud with the air temperature of 29.5–29.0°C, the relative humidity of 66–73 pct, and the wind velocity of about three m/sec. Fairly good agreement was obtained, as shown in Figure 8.

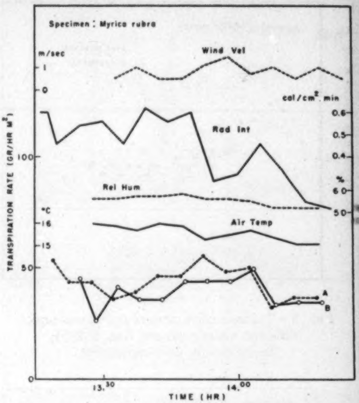

FIG. 11 – Time marches of transpiration rate and meteorological elements under natural conditions; Dec. 4, 1951, field experiment

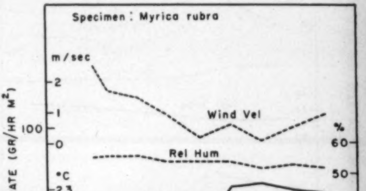

FIG. 12 – Lag period of transpiration rate affected by the variation of solar radiation; Oct. 31, 1951, field experiment

The effect of projection area receiving solar radiation—It is doubtful whether the leaf area or the projection area receiving solar radiation should be applied, in regard to radiation intensity, in calculating the transpiration rate from the amount of water absorbed by a shoot. The examination was carried out in the open with *Myrica rubra*. Figure 9 shows the results of one test. Part A shows the transpiration curve when the projection area is maximum, and part B when it is minimum. A small arrow head shows the instant of changing the direction of a shoot against solar radiation at 12h 49m. As a result, the transpiration rate decreased as much as 13 pct. Another test performed, using three shoots, the various constants of which are indicated in Table 1. The projection area of the first shoot was changed from 305 to 480 cm², equal to a 57.4 pct increase of the initial value, but there was no significant change in its transpiration rate. Furthermore, the transpiration rates of shoots C and D are in good agreement in spite of the ratio of projection area to total leaf area for shoot D exceeds shoot C by 7.7 pct. The transpiration rates of shoot A exceed that for shoots C and D by 40 pct in spite of fact that the ratios of projection area to total leaf area for shoot A are smaller than that for C and D, to an extent of 15 to 91 pct. The discrepancy is not accounted for. Thus, we can not say that the transpiration rate of shoot always increases or decreases in direct proportional relation to the ratio of projection area to total leaf area, but at least we have affirmed the fact that the effect of projection area sometimes attains an extent from 0 to 13 pct.

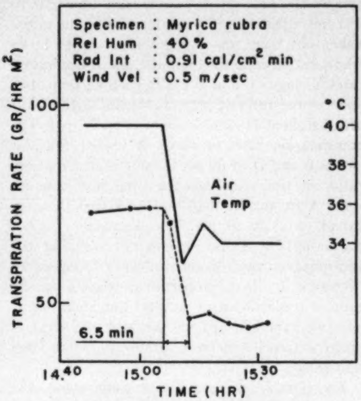

FIG. 15 – Lag period of transpiration rate affected by the variation of air temperature, Feb. 19, 1953

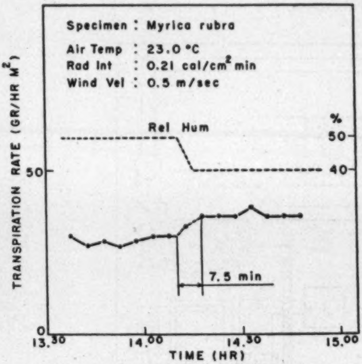

FIG. 16 – Lag period of transpiration rate affected by the variation of relative humidity, Mar. 2, 1953

potometers was varied from 38 to 11.2°C, and that of the other was maintained at a nearly constant value within ±1°C throughout the period of experiment. In spite of these differences in water temperature not only the time marches of transpiration rates in both cut shoots were in parallel tendency but also the discrepancies between two transpiration rates were indistinct. The results are shown in Figure 10. It is suggested that the temperature of water absorbed in the water-conducting system of the stem of cut shoot from its cut end is soon equalized with that of air by heat conduction between bark and air before arriving at the leaves.

The effect of water-supply—The disturbing action of water supply in a measuring pipette will be roughly divided into following three actions: (1) sudden increase of water pressure on cut surface of a shoot; (2) change of water temperature in a potometer; and (3) agitation of water in a potometer. The effects of (1) and (2) on transpiration rate have already been examined, and the results were negative. The effect (3) had not yet been examined. Hence, several examinations were carried out on this effect, but the results were also negative. Thus, the water supply in the course of experiment can be assumed to have little or no effect.

Transpiration rate under natural conditions—It is necessary to investigate the behavior of the transpiration rate under natural conditions before starting our laboratory experiments in order to obtain rough information in advance. Figure 11 is one example of the experimental results with respect to the cut shoots of *Myrica rubra* mounted in potometers.

The total leaf areas of shoots A and B are 1120.6 and 870.5 cm², respectively. There is no significant discrepancy in the values of the transpiration rates.

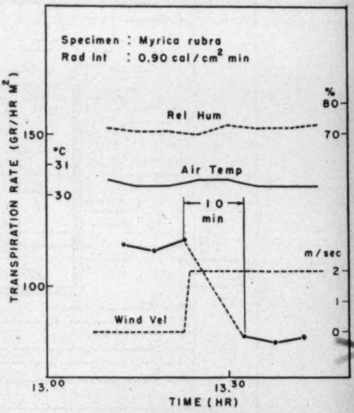

FIG. 17 – Lag period of transpiration rate affected by the variation of wind velocity, July 31, 1953

In addition both transpiration curves follow approximately parallel courses. It can also be seen that the variation of transpiration rate is correlated mainly to the variation of the intensity of solar radiation and the air temperature, the former variation following about ten minutes behind the latter variation.

Figure 12 shows the experimental result of the effect of the solar radiation on transpiration rate. The solar radiation was suddenly screened by a sheet of drawing paper hung about one meter in front of the potometer at the instant shown by a small arrow head (12h 33m). The transpiration rate fell to a value equal to 35.5 gr/hrm² from 53.2 gr/hrm² about ten minutes after the screening. Thus, the transpiration rate of ***Myrica rubra*** varies with the intensity of solar radiation. The time lag was about ten minutes.

As the transpiration rates under natural conditions are affected simultanuously by the complicated change in the environmental conditions as shown above, it is difficult to separate these effects of environmental conditions from such a simple experiment. For that reason, the author has investigated the relation between transpiration rate and various meteorological elements one by one using a hand-made small Göttingen-type wind tunnel in which one can change the radiation intensity, the air temperature, the relative humidity, and the wind velocity at will, or can maintain any of these conditions for a long period.

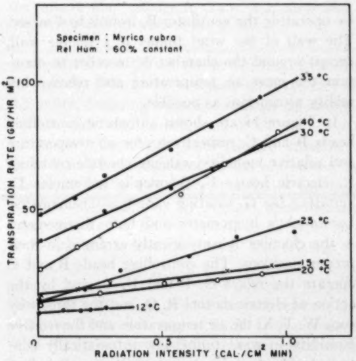

Fig. 20 – Relation between transpiration rate and radiation intensity, Mar. 10 to Apr. 10, 1953; wind velocity, 0.5 m/sec

Apparatus for measuring the transpiration rate as the function of meteorological elements—Figure 13 is a plan view of a wind tunnel. Part A is the measuring chamber enclosed in glass plates at its fore side and upper side. A shoot mounted in a potometer was placed in this chamber after being mounted in a stand, and the potometer readings were taken through the fore side window. The dimensions of this chamber are 63 cm in height, 46 cm in width, and 46 cm in length. The circuit length of wind tunnel is 4.7 m, and the wind velocity at the center of chamber A can be varied,

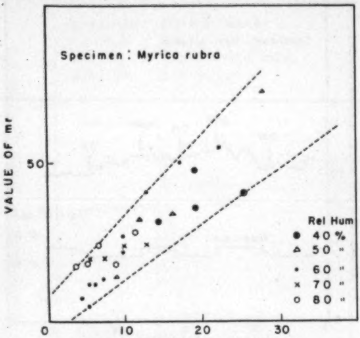

FIG. 21 – Relation between saturation deficit of atmosphere and value of m_r; wind velocity, 0.5 m/sec

by operating the ventilator B, from 0 to 4 m/sec. The wall of the wind tunnel is a double wall, except around the chamber A, in order to maintain the inner air temperature and relative humidity as constant as possible.

In Figure 14 are shown automatic controlling heads B and C, respectively, for air temperature and relative humidity, calcium chloride container E, electric heater F, thermopile radiometer D, agitating fan G, rotating vane-type anemometer, Lambrecht's hygrometer and bulb thermometer in the chamber A conveniently arranged in their proper positions. The controlling heads B and C operate the relays O, P and U, V, and by the action of electric motors R, Q, and the three way cock W, T, X, the air temperature and the relative humidity in wind tunnel are automatically controlled. M is an ice box and S a small boiler; L_1 to L_8 are electric lamps, 500 watts each, and H the water filter. I is a constant-level tank in order to supply water in the water filter H; J is an automatic recorder of the thermopile radiometer D; K_1 to K_{17} show the electric switches. The water supply in a potometer can be maintained by a small rubber tube inserted from the exterior into the chamber A. The small agitating fan G was not operated after the commencement of our experiment for it disturbs the air flow in the wind tunnel.

The lag period of the transpiration rate caused by the sudden change of meteorological elements was investigated by this wind tunnel.

Figures 15 to 17 show the results obtained on *Myrica rubra* by changing the air temperature, the relative humidity, and the wind velocity one by one in the wind tunnel. It takes a few minutes to change these elements in the wind tunnel. In spite of this disadvantage, these lag periods were 6.5, 7.5, and 10 minutes, respectively, as shown. Thus, the lag periods of transpiration rate in case of changing the meterological elements can be considered as 6.5 to 10 minutes.

Relations between transpiration rate and air temperature and relative humidity—With regard to the relation between transpiration rate and air temperature, 15 experiments were carried out on *Myrica rubra* during the period from Feb. 11 to Mar. 9, 1953, under the constant wind velocity of 0.5 m/sec, changing air temperature under constant radiation intensity and relative humidity. With regard to the relation between transpiration rate and relative humidity, 22 experiments were carried out on the same species during the period from Feb. 24 to Apr. 8, 1953 under constant wind velocity of 0.5 m/sec, changing relative humidity under constant radiation intensity and air temperature. The trends appear rather complicated in the relation between transpiration rate and air temperature. It is possible to obtain the experimental formulas necessary to estimate the transpiration rate but the error may be large because of the non-linearity of the trends. Consequently, the author has searched for the other functional relations to obtain more accurate formulas to estimate the transpiration rate.

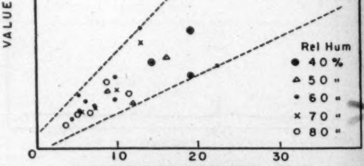

FIG. 22 – Relation between saturation deficit of atmosphere and value of n_r; wind velocity, 0.5 m/sec

Relation between transpiration rate and radiation intensity—Before starting our laboratory experiments on this relation, it is necessary to examine the effect of illumination in order to take readings in the dark and the effect of wave lengths of light on the transpiration rate.

Figure 18 shows the result of an experiment to examine the effect of illumination necessary to take readings in the dark. A shoot of *Myric rubra* was mounted in a potometer and carried into a dark room. After the transpiration rate had attained its steady value, a 100-watt electric lamp about a meter above the shoot was switched on at the instant shown by a small arrow. The light had little effect. A 40-watt lamp was employed to take readings in the dark.

To examine the effect of wave length of light upon transpiration rate, a 250-watt high-pressure mercury lamp was employed in addition to eight incandescent electric lamps which were switched on throughout the experiment. Switching the mercury lamp on and off, four experiments were performed using *Myrica rubra*. Figure 19 shows the results of one test obtained under the conditions of 30°C, 80 pct humidity, and 1 m/sec air velocity. A small effect of the mercury lamp seems to exist, but it is not significant as Iwanov and Thielmann had reported.

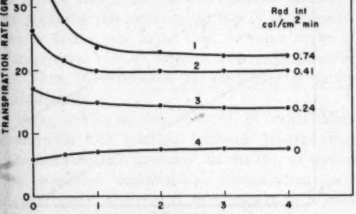

FIG. 23 – Relation between transpiration rate and wind velocity; Jan. 19 to Mar. 17, 1954

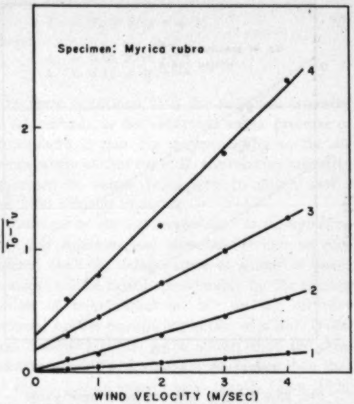

FIG. 24 – Relation between wind velocity and the ratio of wind velocity to ($T_0 - T_v$); curve number corresponds to that of in Fig. 23

With regard to the relation between transpiration rate and radiation intensity, 27 experiments were carried out during the period from Mar. 10 to Apr. 10, 1953 under constant wind velocity of 0.5 m/sec, changing radiation intensity by switching the eight electric lamps on or off under constant air temperature and relative humidity. Only 7 of 27 experimental results are shown in Figure 20. As in this figure, the trends are best represented graphically by straight lines without exception. Let T be the transpiration rate, and R be radiation intensity, then the relation is

$$T = m_r R + n_r \tag{1}$$

where m_r is the slope and n_r the intercept on the ordinate. The values m_r and n_r are both increased with higher air temperature and decreased with higher relative humidity, as it can be seen in the figure, that is, the values m_r and n_r are the functions of air temperature and relative humidity.

Consequently, the method of least squares was employed to obtain the values of m_r and n_r from 27 experiments. The factor having a high degree of correlation was sought. The saturation deficit of atmosphere was found to be a factor having a high degree of linear correlation with the values of m_r and n_r, as shown in Figures 21 and 22. Obviously there is a direct relation between m_r or n_r and saturation deficit, notwithstanding the scatter. The different symbols show that the scatter has no direct connection with relative humidity.

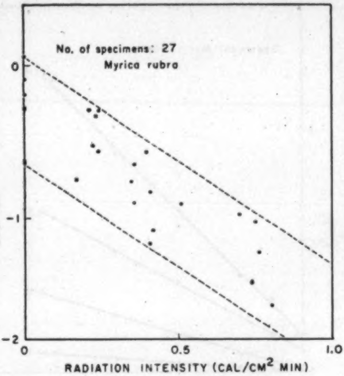

FIG. 25 – Relation between logarithmic value of gradient a and radiation intensity

Again considering the trends as straight lines and employing the method of least squares, the empirical formulas for m_r and n_r were obtained as the function of the saturation deficit H_d of atmosphere. Note that the relation of n_r to H_d was obtained in type of $n_r = s \cdot H_d$, where s indicates the gradient, for the value n_r is the value of transpiration rate under zero radiation intensity and should be considered as zero when H_d is zero.

For *Myrica rubra* (wind velocity = 0.5 m/sec)

$$\left.\begin{aligned} m_r &= 2.13\, H_d + 2.65 \\ n_r &= 1.99\, H_d \end{aligned}\right\} \qquad (2)$$

mean error of m_r = 5.51; mean error of n_r = 5.13.

By substituting these in (1), we obtain an equation representing the transpiration rate T as the function of radiation intensity R (cal/cm^2-min) and saturation deficit H_d (mmHg) for *Myrica rubra* (wind velocity = 0.5 m/sec), as

$$T = (2.13\, R + 1.99)\, H_d + 2.65\, R \qquad (3)$$

mean error of T = 5.60

The saturation deficit of atmosphere H_d can be represented as the function of saturated vapor pressure e_s (mmHg) and relative humidity $H_r \times 100$, as

$$H_d = e_s\,(1 - H_r) \qquad (4)$$

By (3) and (4), we can easily estimate the transpiration rate of *Myrica rubra* under wind velocity of 0.5 m/sec for any radiation intensity, air temperature, and relative humidity.

Relation between transpiration rate and wind velocity—In regard to this relation, 27 experiments were carried out during the period from Jan. 19 to Mar. 17, 1954 with respect to ***Myrica rubra***. Only four experimental results are shown in Figure 23.

The transpiration rate decreases rapidly with higher wind velocity within the range of 0–1 m/sec and approaches a constant value asymptotically within the range of 1–4 m/sec. Furthermore the rate of decrease in transpiration rate diminishes with lower intensity of radiation except in case of 0 cal/cm^{2}min. In this case, 0 cal/cm^{2}min, the transpiration rate increases with higher wind velocity.

In order to obtain the empirical formula for these curves, let us put v as the wind velocity and represent the transpiration rate at $v = 0$ with T_0 and at $v = v$ with T_v, and calculate the value of $v/(T_0 - T_v)$. The rleation between this value and wind velocity can be best represented by a straight line, as shown in Figure 24. Hence, the trends can be represented by

$$v/(T_0 - T_v) = a \cdot v + b \qquad (5)$$

where a is the gradient of the straight line and b the intercept on the ordinate. The values of a and b decrease with higher intensity of radiation. The method of least squares was employed to obtain the values of a and b with respect to the 27 experiments. It was found that the logarithmic values

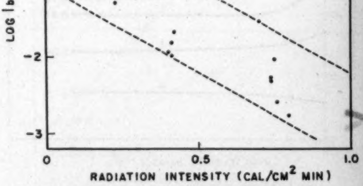

FIG. 26 – Relation between logarithmic value of Y-intercept b and radiation intensity

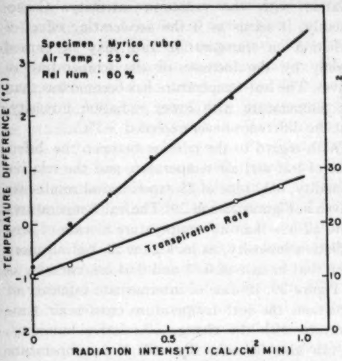

FIG. 27 – Relations between the difference of leaf and air temperature or transpiration rate and radiation intensity; Mar. 28, 1953, laboratory experiment; air temperature, 25°C; relative humidity, 80 pct; wind velocity, 0.5 m/sec

of a and b were in linear relation with the radiation intensity, as shown in Figures 25 and 26. The gradient and the value of intercept on the ordinate were calculated by the method of least squares, and the empirical formula of the transpiration rate T (gr/hrm²) were obtained from (5) as the function of wind velocity v (m/sec) and radiation intensity R (cal/cm² min) for *Myrica rubra*, as follows

$$T_v = T_0 \mp v/(0.55 \times 10^{-1.37R} \cdot v + 0.32 \times 10^{-2.35R}) \qquad (6)$$

where T_0 (gr/hrm²) is the transpiration rate under zero wind velocity and it is the function of air temperature, relative humidity, and radiation intensity. The positive sign after T_0 in (6) should be applied only in case of zero radiation intensity. By applying this equation to the 27 experiments one by one, it was found that the mean errors of transpiration rate lie between 0.02 and 0.35 gr/hr m². Thus, (6) represents the experimental results satisfactorily.

Now, modifying the data of 27 experiments concerning the relation between transpiration rate and radiation intensity, by the (6), we obtain the equation representing transpiration rate T_0 (gr/hrm²). The results with respect to *Myrica rubra* are as follows

$$T_0 = (2.09\,R + 1.67)\,H_d + 35.62\,R \qquad (7)$$

where

$$H_d = e_s\,(1 - H_r)$$

and

$$T = T_0 \mp v/(a \cdot v + b) \qquad (8)$$

where

$$a = 0.55 \times 10^{-1.37R}$$
$$b = 0.32 \times 10^{-2.35R}$$

In these equations, R is the radiation intensity in cal/cm²min, e_s the saturated vapor pressure of atmosphere in mm Hg corresponding to the air temperature at that time, H_r the relative humidity expressed in values from zero to unity, and v the wind velocity in m/sec.

Relations of the leaf temperature to transpiration rate and meteorological elements—It can be considered that the temperature of a leaf in direct sunlight will be raised considerably by the heating action of solar radiation, but on the contrary reduced by the transpiring action of a leaf. *Miller* and *Saunders* [1923] have shown that the temperature of wilted leaf is always higher than that of turgid leaf in case of crop plants. *Clum* [1926] has shown that the temperature of leaves of *Fuchsia speciosa*, *Phaseolus vulgaris*, *Brassica oleracea*, and *Syringa vulgaris* were nearly always warmer than the air during the day, and in direct sunlight they were frequently warmer than the air by 5 to 10°C. *Copeland* [1932] has measured the temperature of the leaves of chaparral shrubs by wrapping a leaf around the bulb of a ordinary thermometer and had reported that the temperature of the leaves in direct sunlight was sometimes higher by as much as 10°C than the shade temperature. *Martin* [1935] has also measured the leaf

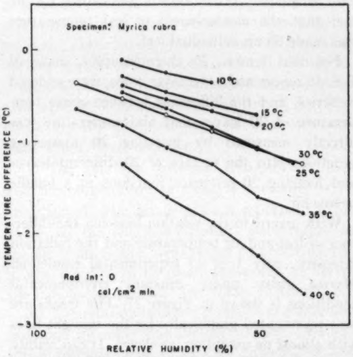

FIG. 28 – Relations between the difference of leaf and air temperature and air temperature and relative humidity; Mar. 26 to Apr. 8, 1953, laboratory experiment; wind velocity, 0.5 m/sec.

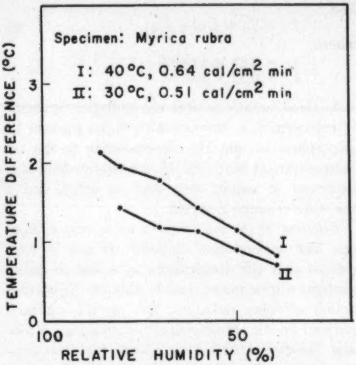

FIG. 29 – Relation between the difference of leaf and air temperature and relative humidity; Mar. 26 to Apr. 8, 1953, laboratory experiment; wind velocity, 0.5 m/sec

temperature of *Helianthus annuus* using thermocouple and reported "the temperature of leaves hanging nearly at right angles to the Sun's rays in the open averaged about 1°C above that of the air, while that of leaves under tent was about 5°C below." Thus, the leaf temperature varies widely with the amount of transpiration and the change of environmental conditions. The regular relations of the leaf temperature to transpiration rate or to meteorological elements had not yet been found. The irregularity of the results was caused by the fact that the measurement of leaf temperature was made on an individual leaf.

For that reason, 20 thermocouples, made of B.S. 36 copper and constantan wires, were soldered in series, and the difference between mean temperature of 20 leaves and air temperature was directly measured by inserting 20 measuring junctions into the surface of 20 different leaves and hanging 20 reference junctions in a bundle in free air.

With regard to the relation between the difference of leaf and air temperature and the radiation intensity, only 1 of 13 experimental results on *Myrica rubra* under constant environmental conditions is shown in Figure 27. The trends are best represented graphically by the straight lines with almost no exception, as shown. It can readily be understood that the difference of leaf and air temperature is in direct proportion to the transpiration rate. The transpiration rate is also in linear relation with the radiation intensity. Consequently, it seems as if the accelerating effect of radiation on transpiration rate may be caused mainly by the increase of the temperature of leaves. The leaf temperature has become less than air temperature with lower radiation intensity, but the difference never exceeded −3°C.

With regard to the relation between the difference of leaf and air temperature and the relative humidity, only nine of 25 experimental results are shown in Figures 28 and 29. The leaf temperatures were all less than air temperature in case of zero radiation intensity, as in Figure 28, but all more than that in case of 0.51 and 0.64 cal/cm^{2}min, as in Figure 29. In case of intermediate intensity of radiation, the leaf temperature crosses air temperature with the change of relative humidity. It can also be seen that the leaf temperature acceleratively decreases with higher air temperature and increases almost in linear trends with the increase of relative humidity. This tendency is quite opposite to that of the transpiration rate.

From these results, it can be suggested that the leaf temperature would be decreased linearly with the increase of the saturation deficit of atmosphere and with the decrease of radiation intensity. This was confirmed by dividing the radiation intensity in steps of 0.1 cal/cm^{2}min and rearranging the experimental data in these steps, but only a part of the results were shown in Figure 30.

The values of radiation intensity indicated in

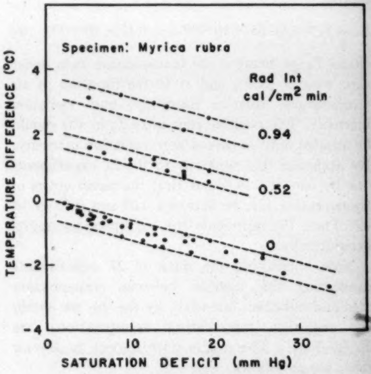

FIG. 30 – Relation between the difference of leaf and air temperature and saturation deficit of atmosphere; wind velocity, 0.5 m/sec

the figure are the mean value of radiation intensity corresponding to each plotted point. Now, we can see that not only the leaf temperature decreases in nearly direct proportion to the saturation deficit but also the whole trend rises with higher radiation intensity, as has already been expected. The gradients of trends seem to have no connection with radiation intensity. Provided that the gradients are constant with regard to the radiation intensity, the inclinations of the straight lines representing the relation between the difference of leaf to air temperature and the radiation intensity will have no relation with air temperature and relative humidity under constant wind velocity.

With regard to the relation between the difference of leaf and air temperature and the wind velocity, only four of 25 experimental results are shown in Figure 31. These trends closely resemble that of the relation between transpiration rate and wind velocity. The leaf temperature decreases rapidly with higher wind velocity within the range of 0–1 m/sec and very slowly beyond this wind velocity when the radiation intensity is not zero, but on the contrary increases when the radiation intensity is zero. This effect is violent with higher radiation intensity. It seems probable that the wind causes the circulation of air around the leaves to conduct heat from air to the leaf surface when the temperature of the leaf is lower than that of surrounding air but to conduct heat from leaf surface to air when the temperature of leaves is higher than that of surrounding air, until the equilibrium is attained between the leaf temperature and the air temperature. It also seems probable that the transpiration rate lags behind the change of the leaf temperature.

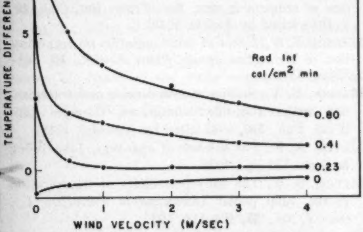

FIG. 31 – Relation between the difference of leaf and air temperature and wind velocity; Jan. 21 to Mar. 17, 1954; laboratory experiment

As we have described above, there are close correlations between mean temperature of leaves, transpiration rate, and meteorological elements. The relation between them follows a regular trend. It should be noted that the mean temperature of leaves had been determined by only 20 thermocouples inserted into 20 different leaves, and the total number of leaves amounts to 80–250 in case of shoot of *Myrica rubra*. Accordingly, it is still doubtful whether the measured values will give the true mean temperature of whole leaves of a shoot or not.

Summary of the experimental results—In this report, the relations between transpiration rate and meteorological elements were studied in order to derive the experimental formulas useful to estimate the total amount of transpiration from a forest under optional meteorological conditions. The following results were obtained.

(a) The transpiration rate of a shoot mounted in a potometer agrees within ±2.4 pct of that of a potted plant and the stomatal openings are in a healthy state provided one or two hours has elapsed after the cut of a branch, and wilting has not occurred.

(b) The effects of cutting process, water pressure, projection area against solar radiation, water temperature, water supply, were examined in order to confirm the reliability of potometer method. The cutting process was different for various species and at least 0–13 pct change in transpiration rate in case of changing projection area against solar radiation was found, but the effect of water pressure, water temperature, and water supply were negative.

(c) The relations between transpiration rate and air temperature or relative humidity were investigated. The details are not reported in this paper, for the relations especially with regard to the air temperature, were rather complicated and it was thought to be disadvantageous to derive the empirical formula by these relations.

(d) The relation between transpiration rate and radiation intensity was further studied. The empirical formula, $T = (2.13\ R + 1.99)\ H_d + 2.65\ R$, was obtained for *Myrica rubra*, under the constant wind velocity of 0.5 m/sec, where R is the radiation intensity, and H_d the saturation deficit of atmosphere.

(e) The relation between transpiration rate and wind velocity was studied. The empirical formulas necessary to estimate the transpiration rate T under optional meteorological conditions were

$$T = T_0 \mp v/(0.55 \times 10^{-1.37R\cdot v} + 0.32 \times 10^{-2.35R}) \quad (6)$$

$$T_0 = (2.09\ R + 1.67)\ H_d + 35.62\ R \quad (7)$$

(f) Finally, the relations of the leaf temperature to transpiration rate and meteorological elements were studied, using 20 pairs of copper-constantan thermocouples in series, and showed that the linear relationship holds between leaf temperature and transpiration rate and the systematic relations hold between leaf temperature and meteorological elements closely resembling the relation between transpiration rate and meteorological elements.

Acknowledgments—The author wishes to express his gratitude to U. Nakaya of Hokkaido University who had kindly taken a great deal of pains to help the author throughout the research, to A. Higashi of the same University, to the late M. Akiba of Tokyo University, and to M. Ohmasa, the Director of the Government Forest Experiment Station in Tokyo, who had kindly guided the author in preparing the report.

The Total Transpiration from a Forest

YOSHITO YAMAOKA

Abstract—The investigation on the relation between total leaf weight and breast-height diameter is necessary to estimate the total transpiration. The method of estimating the total leaf weight of *Cryptomeria japonica* was discussed, and this was found to be proportional to the square of the breast-height diameter. The relations between transpiration rate and the meteorological elements regarding to this species were also investigated, and the empirical formulas necessary to estimate the total transpiration were obtained. Finally, a stand of 740 *Cryptomeria japonica* (4376 sq m; about 1.1 ac) 45 years old was selected, for example, and the total leaf weight was estimated at 69 tons and the total transpiration at 1.80 ton/hour in case of air temperature, 26.6°C; relative humidity, 80 pct; wind velocity, 3.5 m/sec; and radiation intensity, 1 cal/cm^2 min. This value was compared with the water loss from various types of surfaces to show no serious error exists in our estimation.

The relations between leaf temperature and transpiration rate and meteorological elements were also investigated.

Introduction—In the previous report [*Yamaoka*, 1957] the experimental formulas necessary to estimate the total transpiration from a forest of *Myrica rubra* were obtained. Unfortunately, no reforestation of this specis can be found in our area. This species was selected only for the reason that it is grown in the yard near our laboratory and is one of the easiest species in treatment of their shoots. Using this species, the fundamental research for estimating the total transpiration from a forest has been accomplished. Accordingly, the author intends to estimate the total transpiration from a stand or forest of *Cryptomeria japonica* in Namera National Forest, Compartment 27, Yamaguchi District, Japan, where the author once surveyed the distribution of breast-height diameters.

In order to carry out the work, it is necessary to obtain the relation between total leaf area and breast-height diameter of this species. There have been several investigations in regard to the measurement of total leaf area of broad-leaved trees and conifers performed by, *Baker* [1948], *Buchanan* [1936], *Burger* [1938], *Dengler* [1937], *Kadota* [1950], *Kittredge* [1944], *Kozlowski* [1943], *Yamaoka* [1952], and others, but there has been no investigation useful to our work in regard to *Cryptomeria japonica*. Consequently, the author has measured the total leaf amount of this species. Since it was difficult to measure the total leaf area because its countless short needles lie upon one another and have no distinct boundary around each needle, the author was compelled to measure the total leaf weight instead of the total leaf area. It has already determined from several other species that a linear relation holds between leaf area and its weight, so it can be expected that the same relation will hold in case of this species.

Boundary of leaves—There is no distinct boundary between leaves and green bark on the stem of a twig of the *Cryptomeria japonica* unlike the broad-leaved trees and pine trees. The green bark is stripped off in irregular shape when the needles are torn from the stem of the twig. In addition, it is not only almost impossible to count the number of needles, but also to tear off these innumerable needles.

Examining the branch in detail, it is found that the color of bark with needles is green and without needles is brown. The boundary between these barks is distinct. As most of the green bark is stripped off with the needles, the author decided to measure the total leaf weight together with the green bark. It is almost impossible to strip off all of the green bark together with the needles, therefore the author has searched for some convenient relation between total leaf amount and another factor which makes it possible to measure the total leaf weight. It was found that the total weight of a branch cut off at the boundary of green and brown bark is directly related to its woody tissue (Fig. 1).

The total weight of the woody tissue is approximately ten per cent of the total weight of a branch having green bark. Accordingly, it became possible to determine the total leaf weight by subtracting ten per cent of the whole weight of a branch having green bark.

Relations of the total leaf weight to age and sectional area of stem just under the crown—It has already

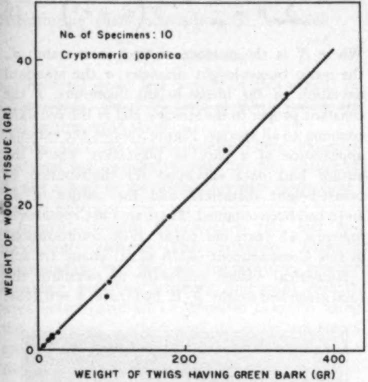

FIG. 1 – Relation between fresh weight of twig having green bark and fresh weight of their woody tissue; surveyed in Nov. 1952

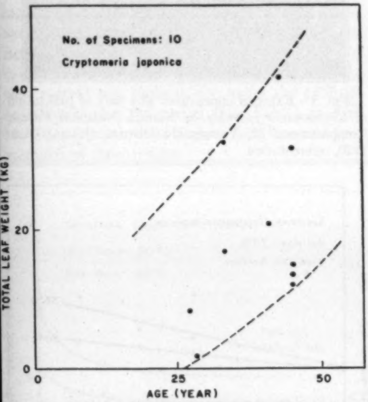

FIG. 2 – Relation between total leaf weight and age; surveyed Nov. 26 to Dec. 4, 1952

been described [*Yamaoka*, 1952] that the total leaf area of some broad-leaved trees and pine trees were in direct proportion to the sectional area of stem just under the crown, but that there was no significant correlation between the total leaf area and age. Accordingly, similar relations for *Cryptomeria japonica* were investigated.

A large part of *Cryptomeria japonica* actually surveyed were the trees growing closely in a row and had been cut at the tips of the stem several times, but not in the past five or six years. The results obtained from ten of these *Cryptomeria japonica* with ages from 27 to 45 years, are shown in Figures 2 and 3. Figure 2 shows the relation between total leaf weight and age. Figure 3 shows the relation between total leaf weight and sectional area of stem just under the crown.

The values of total green leaf weight used in Figures 2 and 3 were obtained by subtracting ten per cent from the total weight of branches having green bark. Cones and flowers were removed before weighing. The trend is linear in Figure 3, but no significant correlation can be seen in Figure 2, which is consistent with the relations for broad-leaved trees and pine trees. Let us consider the trend in Figure 3 as a straight line passing through the origin and calculate its gradient k by means of the method of least squares. The relation between total green leaf weight W (Kg) and diameter of stem just under the crown d_0 (cm) can be expressed by

$$W = k \cdot \frac{\pi}{4} \cdot d_0^2 = 0.2134 \times \frac{\pi}{4} \cdot d_0^2 \qquad (1)$$

mean error of $W = 1.306$ Kg

It has already been reported [*Yamaoka*, 1952] that the breast-height diameter d (cm) can be expressed by $d = m \cdot d_0$, where m is the constant

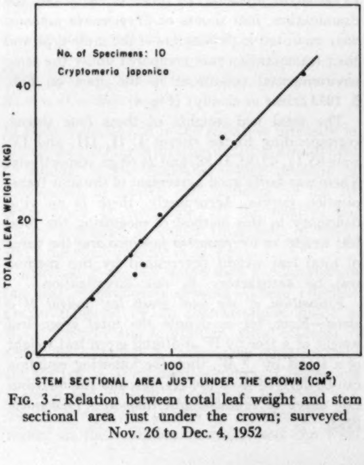

FIG. 3 – Relation between total leaf weight and stem sectional area just under the crown; surveyed Nov. 26 to Dec. 4, 1952

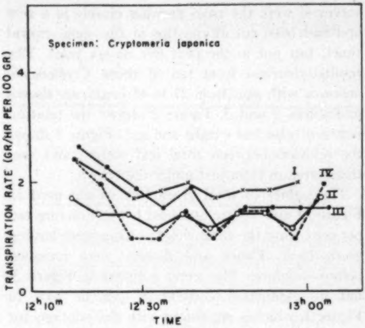

FIG. 4 - Amount of transpiration per 100 gr of green leaf weight per hour

common to all species. The value of m was calculated from 31 experimental data by means of the method of least squares and was found to be 1.110.

Accordingly, we have

$$d = m \cdot d_0 = 1.110\, d_0 \qquad (2)$$
$$\text{mean error of } d = 0.80 \text{ cm}$$

Examination of the method for measuring the total leaf weight—It is necessary to examine whether the total leaf weight determined by means of the convenient method described above will serve satisfactorily to measure the transpiration rate of *Cryptomeria japonica*. In order to carry out the examination, four shoots of *Cryptomeria japonica* were mounted in potometers of the same type and their transpiration rate compared under the same environmental conditions in the open on Feb. 5, 1953 (clear or cloudy) (Fig. 4).

The total leaf weights of these four shoots, corresponding to the curves I, II, III, and IV, were 85.11, 42.30, 31.88, and 24.68 gr, respectively. There was fairly good agreement of the four transpiration curves. Accordingly, there is no vital deficiency in this method of measuring the total leaf weight of *Cryptomeria japonica* and the value of total leaf weight determined by this method will be satisfactory in our investigation.

Estimation of the total green leaf weight of a stand—Now, let us denote the total green leaf weight of a tree by W and total green leaf weight of a stand by $\sum W$, then the following equation can be derived from the (1), (2), and the distribution curve of breast-height diameters [*Yamaoka*, 1952].

$$\sum W = \frac{k}{m^2} \cdot \frac{\pi}{4} \cdot N\left(d_m^2 + \sigma^2\right) \qquad (3)$$

Where N is the number of trees in a stand, d_m the mean breast-height diameter, σ the standard deviation of the breast-height diameters, k the constant proper to the species, and m the constant common to all species. Figure 5 shows the external appearance of a part of plantation where the author had once surveyed the distribution of breast-height diameters and the values of d_m and σ had been obtained. There are 740 *Cryptomeria japonica* 45 years old (Mar. 1910, reforestation) in this Compartment (4376 sq m; about 1.1 ac).

Numerical values necessary to calculate the total green leaf weight $\sum W$ by (3) are: $k = 0.2134$,

FIG. 5 - External appearance of a part of plantation of *Cryptomeria japonica* in Namera National Forest, Compartment 27, Yamaguchi District, Japan; Mar. 1910, reforestation

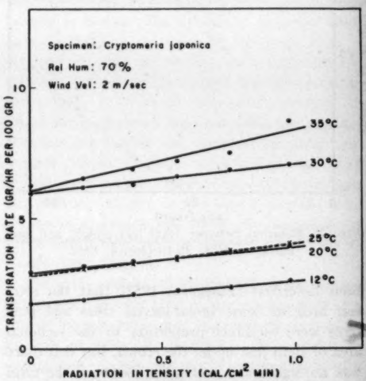

FIG. 6 - Relation between transpiration rate and radiation intensity; Feb. 24 to Apr. 16, 1954, laboratory experiment

$m = 1.110$, $N = 740$, $d_m = 24.45$ cm, $\sigma^2 = 86.80$. Substituting these values into (3), we have

$$\sum lW = 68914 \text{ Kg} \tag{4}$$

as the total green leaf weight of this stand. In other words, about 69 tons of green leaves are held on this small stand.

Note that the value obtained here indicates the total leaf weight in 1951 for the values of d_m and σ used in the calculation were those measured in 1951.

Relations between transpiration rate and meteorological elements—The relations between transpiration rate and air temperature, relative humidity, radiation intensity, and wind velocity were investigated on *Cryptomeria japonica* using the potometer method and the same apparatus used for *Myrica rubra* [*Yamaoka*, 1957]. As the trends closely resembled the trends in case of *Myrica rubra*, the author derived the empirical formulas from the relations between transpiration rate and radiation intensity and wind velocity.

The effects of illuminating lamps to take readings in the dark and the wave lengths of light were first examined and found little or no effect. Accordingly, 19 and 26 experiments with regard to the radiation intensity and the wind velocity were carried out, respectively, under the artificial radiation during the period from Feb. 1 to Apr. 16, 1954. Figures 6 and 7 show only five and four examples of these results.

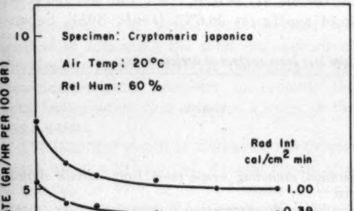

FIG. 7 – Relation between transpiration rate and wind velocity; Feb. 1 to Mar. 31, 1954, laboratory experiment

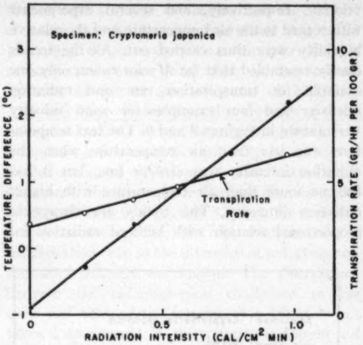

FIG. 8 – Relations between the difference of leaf and air temperature or transpiration rate and radiation intensity; Apr. 14, 1954, laboratory experiment; air temperature, 35°C; relative humidity, 40 pct; wind velocity, 2 m/sec

Considering now, the trends in Figure 6 as straight lines and the wind velocity v in proportional relation with the value $v/(T_0 - T_v)$, where T_0 represents the transpiration rate at zero wind velocity and T_v at any wind velocity v, the following empirical formulas can derived as in the case of *Myrica rubra* [*Yamaoka*, 1957].

$$T_v = \mathrm{T}_0 \mp v/(2.77 \times 10^{-0.96\, R} \cdot v + 2.16 \times 10^{-1.45\, R})$$

where

$$T_0 = (0.14\, R + 0.35)\, H_d + 3.08\, R \tag{5}$$

and

$$H_d = e_s\,(1 - H_r)$$

In these equations, R is the radiation intensity in cal/cm²min, H_d the saturation deficit of atmosphere in mmHg, e_s the saturated vapor pressure of atmosphere in mmHg corresponding to the air temperature at that time, H_r the relative humidity expressed in values from zero to unity, and v the wind velocity in m/sec.

Relations of the leaf temperature to transpiration rate and meteorological elements—These relations are investigated by 20 thermocouples made of B.S. 36 copper and constantan wires, soldered in series, by inserting 20 measuring junctions into the surface of 20 different needles of *Cryptomeria japonica* and hanging 20 reference junctions in a bundle in free air. 16 and 21 experiments with regard to the radiation intensity and the wind velocity, respectively, and several experiments with regard to the air temperature and the relative humidity were thus carried out. As the trends closely resembled that for *Myrica rubra*, only one example for transpiration rate and radiation intensity and four examples for wind velocity were shown in Figures 8 and 9. The leaf temperature was less than air temperature when the radiation intensity was zero or low, but it has become more than air temperature with higher radiation intensity. The trends are always in proportional relation with both of radiation intensity and transpiration rate. Therefore, it seems as if the accelerating effect of radiation on transpiration rate may be due mainly to the increase of the temperature of needles.

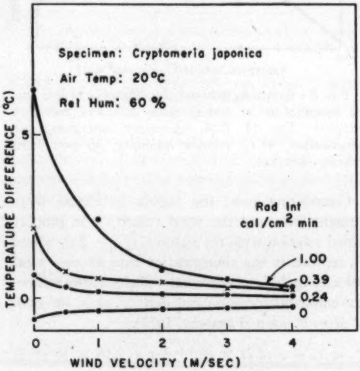

FIG. 9 – Relation between the difference of leaf and air temperature and wind velocity; Feb. 1 to Mar. 31, 1954, laboratory experiment

The relation between leaf temperature and wind velocity also resembled that of transpiration rate and wind velocity, as in case of *Myrica rubra*. It also seems probable that the transpiration rate follows the change of the leaf temperature.

Thus the trends show the close correlations between mean temperature of leaves, transpiration rate, and meteorological elements, and the relations between them follow regular trends.

Estimation of the total transpiration from a stand—According to the statistics during the period of recent 30 years in Shimonoseki, Japan, the mean meteorological conditions in August [*Tokyo Astronomical Observatory*, 1953] are: mean air temperature, 26.6°C; mean relative humidity, 80 pct; mean wind velocity, 3.5 m/sec.

It will not be the same in Namera National Forest. We have employed these values for the present in order to show how to estimate the total transpiration from a stand of *Cryptomeria japonica*, as there are no meteorological data in Namera National Forest. The intensity of radiation as 1 cal/cm²min was assumed.

The numerical values necessary to calculate the transpiration rate of *Cryptomeria japonica* under above meteorological conditions are: R = 1 cal/cm²min, H_r = 0.80, v = 3.5 m/sec, and e_s = 26.14 mmHg (at 26.6°C) [*Fowle*, 1934]. Substi-

TABLE 1 – *Comparison of the amount of water loss from surface of various types*

Type	Amount of water loss			Remarks
	per 4376 m²	per km²	per acre	
	ton/hr	ton/hr	ton/hr	
Stand of *Cryptomeria japonica*	1.80	411.32	1.66	Transpiration excluding evaporation from surface during August
Paddy field	1.06	242.22	0.98	Transpiration with evaporation from water-surface; mean value during August 1933
Water	0.16	36.56	0.15	Mean water temperature, 15.2°C
Water	2.20	502.72	2.03	Mean water temperature, 23.8°C
Grassland	0.37	84.55	0.34	Transpiration and evaporation; mean soil temperature, 12.5°C
Grassland	0.72	164.53	0.67	Transpiration and evaporation; mean soil temperature, 18.8°C
Wet soil	1.38	315.34	1.28	Perfectly wet soil; mean soil temperature, 18.6°C
Wet soil	0.76	173.67	0.70	When only thin surface layer was dried; mean soil temperature, 14.5°C
Wet sand	0.66	150.82	0.61	When only thin surface layer was dried; mean sand temperature, 23.6°C

tuting these values in (5), we have

$$T_{3.5} = 2.61 \text{ gr/hr per 100 gr of green leaf weight} \quad (6)$$

Accordingly, the total amount of transpiration per hour from this stand (4376 sq m; 1.1 ac) is calculated by (4) and (6) as

$$2.61 \times 10^{-5} \times 68914 = 1.80 \text{ ton/hour}$$

In order to compare this amount of water loss by transpiration with that of evaporation and transpiration from the surface of paddy field, water, grassland, wet soil, and wet sand, of the same area, that is, 4376 sq m, these materials (except paddy field) were filled into a culture dish, 11.7 cm in inner diameter and 2.7 cm in its depth, one by one, having previously poured in it an adequate quantity of water. This dish was buried at the center of a china vat, 36 cm x 28 cm x 4.6 cm in its dimensions, also filled with the same material in order to minimize the edge effect. The china vat with culture dish in its center was then placed in the wind tunnel and only this culture dish was weighed at an interval of 30 minutes under constant radiation intensity, air temperature, relative humidity, and wind velocity, of 1 cal/cm²min, 26.6°C, 80 pct, and 3.5 m/sec respectively. And the results were calculated in ton per hour per 4376 sq m.

These results are shown in Table 1. The amount of water loss from paddy field was calculated from the mean value of the experimental data during August 1933, by *Kano* amd *Matsuo* [1934; *Takata*, 1954].

Conclusions—The author has described the method of measuring the total leaf amount of *Cryptomeria japonica* and the derivation of the empirical formulas necessary to estimate the total transpiration of a stand or a forest of the same species.

The total leaf weight of a stand of 740 *Cryptomeria japonica* 45 years old, its total ground area amounting to 4376 sq m in Namera National Forest, Compartment 27, Yamaguchi District, Japan, was estimated at about 69 tons in 1951. The water loss by transpiration from this stand under such meteorological conditions as; radiation intensity, 1 cal/cm²min; air temperature, 26.6°C; relative humidity, 80 pct; wind velocity 3.5 m/sec; was calculated and estimated to be 1.80 ton per hour.

This amount was compared with the water loss from the surface of paddy field, water, grassland, wet soil, and wet sand, of the same area, that is, 4376 sq m. It was shown that the amount of water loss by transpiration from this stand (excluding direct evaporation from the Earth's surface) was larger than that of the various surfaces, except in case of water of 23.8°C.

It was thus shown that the amount of total transpiration from a stand or a forest under certain meteorological conditions can easily be estimated if the standard deviation of the breast-height diameters, the mean breast-height diameter, the number of trees in a stand or a forest, the constant proper to the species, and the relations of the transpiration rate to the intensity of radiation and the wind velocity are known. The discrepancy between the meteorological conditions in the open and that of the interior of a stand is not taken into account in this report. It should not be neglected in case a more accurate estimation is desired.

Acknowledgments—The author wishes to express his gratitude to U. Nakaya of Hokkaido University who had kindly taken a great deal of pains to help the author throughout the research, to A. Higashi of the same University, to late M. Akiba of Tokyo University, and to M. Ohmasa, the Director of the Government Forest Experiment Station in Tokyo, who had kindly guided the author in preparing the report. The author also wishes to give thanks to T. Tamura and H. Tokushige.

A Method for Determining the Average Precipitation between Curved Isohyets*

GUY A. FRANCESCHINI

Abstract—A method is presented to enable the hydrologist to make more accurate computations, based on the isohyetal method, of precipitation volume over an area. Essentially, the method is concerned with determining the average precipitation value in areas between curved isohyets. The technique is developed for circular concentric isohyets but is extended to other cases. An overlay-nomogram is utilized for the computations.

Introduction—The volume of precipitation over the area between two isohyets is ordinarily assumed to be equal to the product of the enclosed horizontal area and the arithmetic average of the bounding isohyets. In the case of straight and parallel isohyets this assumption is correct. However, when the isohyets are curved, appreciable error may result.

Normally, because of the nature of precipitation measurements and the spottiness of data, no greater accuracy should be required of volumetric computations than that attained by using the arithmetic average. However, because of recent promising developments of radar techniques for determining total storm isohyets, it soon may be possible to determine a much improved areal distribution of precipitation for any storm [*Tarble*, 1957]. In anticipation of this development, it therefore seems necessary to consider a more refined method of computing the water volume. Consideration should take into account the effect of curvature of the isohyets on the proper average precipitation value used in the isohyetal method.

An approach to the problem is here considered. The simple case of circular concentric isohyets is treated, and a method is presented for the determination of a more realistic average precipitation value under this somewhat idealized condition. The method is then extended to non-circular and non-concentric isohyets.

Theory—Consider the hatched area A in Figure 1, bounded by two isohyets, R_a and R_b, and two radials, OP and OP', making an angle θ with each other such that they intercept portions of the isohyets that are circular and concentric. R_a and R_b are at distances a and b, respectively, from 0.

The volume of precipitation involved in this area A may be expressed as

$$V = \bar{R}A = \bar{R}(b^2 - a^2)\theta/2 \qquad (1)$$

where $\bar{R}$ is defined as the average precipitation over the area; θ is in radians.

The volume may also be expressed by the integral

$$V = \theta \int_a^b Rr\,dr \qquad (2)$$

where r is the radius to points included in area A, and R is the precipitation depth at similar points.

If we combine equations (1) and (2) and solve for $\bar{R}$ we get

$$\bar{R} = [2/(b^2 - a^2)] \int_a^b Rr\,dr \qquad (3)$$

Integration of (3) is possible if we know R as a function of r ($R \neq$ constant). Let us assume R to vary linearly as follows

$$R = R_a + (dR/dr)\,dr \qquad (4)$$

where $dR/dr = (R_b - R_a)/(b - a) = \Delta R/(b - a)$, and $dr = (r - a)$.

Substitution of (4) into (3) gives

$$\bar{R} = [2/(b^2 - a^2)] \cdot \int_a^b r[R_a + (r - a)\Delta R/(b - a)]\,dr \qquad (5)$$

Eq. (5) may be integrated directly, and upon simplification reduces to

$$\bar{R} = R_a + [1 + b/(b + a)]\,(R_b - R_a)/3 \qquad (6)$$

or

$$\bar{R} = R_a \mp ([1 + b/(b + a)]/3)\,|\Delta R| \qquad (7)$$

The minus sign is used when R decreases with increasing r, which is the usual case; the plus sign when R increases outward.

---

* This is a contribution from the Department of Oceanography and Meteorology of the Agricultural and Mechanical College of Texas, Oceanography and Meteorology series number 103.

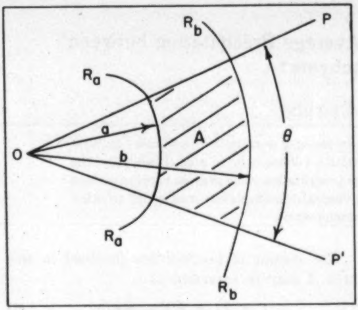

FIG. 1 – The horizontal area A between circular concentric isohyets

Eq. (7) may be simplified to

$$\bar{R} = R_a \mp f\,|\,\Delta R\,| \qquad (8)$$

where

$$f = [1 + b/(b + a)]/3 \qquad (9)$$

It will be noted that $|\,\Delta R\,|$ is the magnitude of the isohyetal interval. Should unit isohyets be drawn the average precipitation value $\bar{R}$ reduces to the sum or difference of the inner isohyet and the dimensionless factor f. The value of f can be quickly obtained by use of a nomogram which is explained in a later section.

The f factor—It may be instructive to consider (9) briefly in a somewhat different light for a better understanding of the construction and use of the nomogram.

If we consider the difference x between the radii of isohyets bounding an area, then

$$x = (b - a) \qquad (10)$$

Substitution of this value of x into the equation for f gives

$$f = [(3a + 2x)/(2a + x)]/3 \qquad (11)$$

In this form the value of f is seen to depend on the radius a of the inner isohyet R_a and the distance x between isohyets bounding the area considered.

The f values fall within the limits $0.50 < f < 0.67$. Table 1 shows the various values as a function of a and x.

The f-factor nomogram—Solutions for the values of f with concentric isohyets of different radii, a and b, are given by the f-factor nomogram (Fig. 2) which was constructed from values given in Table 1.

TABLE 1 – *The factor f for various values of inner radius a and difference x between inner and outer radius (b − a)*

a	x

7	0.51	0.52	0.53	0.54	0.54	0.55	0.56	0.56	0.57	0.57
8	0.51	0.52	0.53	0.53	0.54	0.55	0.55	0.56	0.56	0.56
9	0.51	0.52	0.52	0.53	0.54	0.54	0.55	0.55	0.56	0.56
10	0.51	0.52	0.52	0.53	0.53	0.54	0.54	0.55	0.55	0.56

The nomogram consists of a series of arbitrary concentric circular arcs of different radii (a and b). Along the central vertical axis each arc is connected to others of greater magnitude by horizontal tangent lines. These lines are merely a device to connect one radius with another, that is, a with b, and represent the parameter x. Making the lines tangent was an arbitrary choice. The sloping lines emanating from the origin 0 are lines of constant f. The magnitudes of the f lines are indicated along the scale at the right. These are the only values involved in the computation. The values of a and b are automatically considered by superimposing the nomogram overlay on the isohyetal pattern so that isohyets and circular arcs coincide.

Use of the f nomogram—For practical purposes the nomogram is most useful when made up as a transparent overlay. Any convenient choice of concentric arcs may be included depending on the nature and size of the isohyetal pattern analysed. The areas to be considered are those having curved isohyets.

There are essentially three steps in the use of the overlay. (The section, *Comments*, will amplify these.)

(1) Select the radials so as to include similarly curved isohyets—circular and concentric.

(2) Place the nomogram over the region considered so that any two of its concentric arcs coincide simultaneously with the isohyets bounding the area within the radials.

(3) Read the value of f at the intersection of the line tangent to the arc coincident with the inner

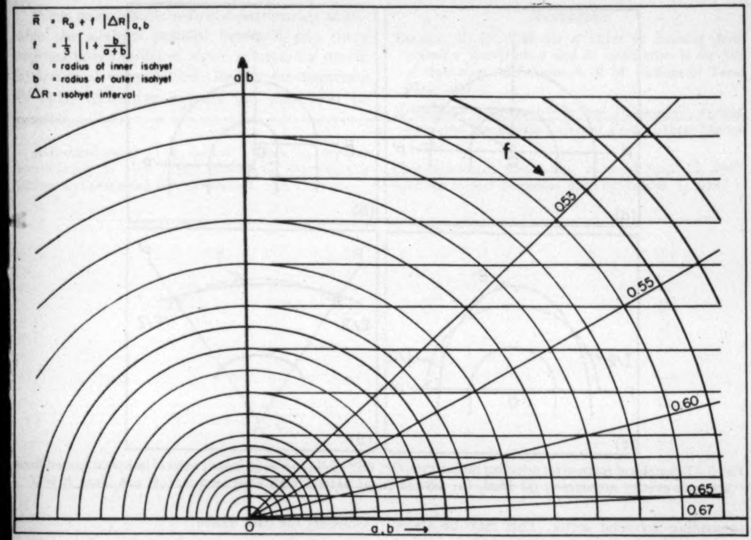

FIG. 2 – The f-factor nomogram for computing average precipitation depth between isohyets of interval Δ R

isohyet, and the circular arc coincident with the outer isohyet.

The value of $\bar{R}$ may then be obtained by using (8), $\bar{R} = R_a \mp f\,|\Delta R|$. This value of $\bar{R}$ then is substituted in Eq. (1), $V = \bar{R}A$, giving the volume of precipitation which has fallen in area A. It must be remembered, A is the horizontal area included by the bounding radials as defined in connection with Figure 1. The quantity A may be obtained either by planimeter or grid methods and should be done after the radials have been selected.

Comments—Since the quantity f, Eq. (11), involves like terms in both numerator and denominator, any map scale factor will cancel, and hence need not be considered. The nomogram therefore may be used directly on all charts of different scales. The only consideration required is of convenient size.

Note that any two isohyets may be considered simultaneously. They need not be of any fixed interval. (As will be seen later, they need not be circular nor concentric.)

In cases where circular and concentric isohyets do not coincide with arcs on the nomogram, intermediate coincident arcs may be interpolated. Further, the isohyets need not form complete circles. All that is required for the ideal case is that the curvature of the bounding isolines remain constant (see Fig. 3a). In regions where the curvature varies it may be possible to divide the area into smaller parts each of which meets the ideal requirement (see Fig. 3b). In any case the radials should be selected first to properly separate areas with different isohyetal curvature.

Although we have been considering a way to treat the simple case of circular isohyets we may apply the method, to a good approximation, to non-circular (elliptic, parabolic, and straight) isohyets. The procedure in these common cases is to first select the radials so as to eliminate straight and parallel isohyets, and include, if possible, those of similar curvature in each sector. The radials of adjoining sectors need not have a common origin but care must be taken to insure no region is excluded nor used in more than one computation. Next, treating each sector separately, select circular arcs on the nomogram which intersect isolines of the sector so that the area of the nomogram sector for each arc equals that of the cor-

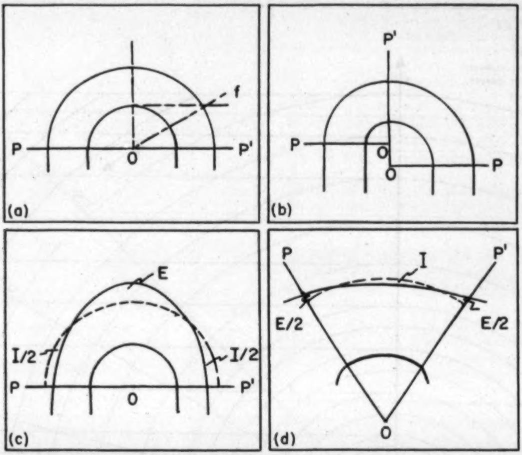

FIG. 3 – Examples of method for selecting radial lines, OP, OP'; solid curves represent pairs of isohyets; dashed lines are from overlay nomogram; (a) ideal; (b) asymmetrical pattern with ideal sectors; (cd) non-ideal, $E = I$

responding isohyetal sector. This may be stated another way. The arc selected should be area preserving, that is, it should exclude from its sector an area E within the isohyetal sector equal to the area I it includes from without the isohyetal sector. Figures 3c and 3d show a few such cases. Care must be used if the patterns are not symmetrical for then the equalizing of areas becomes less accurate. It may be that one of the isohyets is circular in which case the task is halved. Once the area-preserving arcs are selected the value of f will be given at the intersection of the inner arc tangent line, and the outer circular arc.

There are undoubtedly cases which are not amenable to the above considerations, that is, adjacent isohyets having opposite curvatures, and non-parallel straight lines. In such cases the arithmetic average is probably the best resort.

In cases where the curvature of the isohyets reverses sign, or the isohyets oscillate, the arithmetic average of the bounding isohyets may be used for the area included between radials which isolate one wave length of the oscillation, or some integral number of wave lengths. Experience in the use of the overlay will reveal other short-cut techniques and adaptations.

Conclusions—A numerical example will point to the advantage of using the f-factor nomogram. Consider the case where:

$$A = 500 \text{ mi}^2$$

$$R_a = 2 \text{ in}; \qquad R_b = 1 \text{ in}$$

$$b = 4a$$

The volume of water using the arithmetic average precipitation is

$$V = \bar{R}A = 1.5 \times 500 = 750 \text{ in mi}^2$$

Use of the nomogram gives $\bar{R} = 1.4$ in. The volume using this value is

$$V = \bar{R}A = 1.4 \times 500 = 700 \text{ in mi}^2$$

The difference in volumes, 50 in mi², is equivalent to 1.16×10^8 ft³ or about 8.69×10^8 gal, an appreciable amount for a small basin, although only about seven per cent of the total amount.

In general, since total storm isohyetal patterns consist of one or more centers of high precipitation (rather than low centers), values obtained by the suggested computations will be smaller than those computed using the arithmetic average precipitation. The greatest deviations will occur in areas where the inner isohyet has a small radius, and the distance between isohyets is large.

When more reliable isohyetal patterns are available the methods outlined here will give more representative values of water volumes for use in hydrological computations. Recent developments in radar techniques indicate this may soon be possible.

Acknowledgement—The author wishes to express appreciation to Mrs. Peggy Howell for drawing the figures and preparing the manuscript.

The Thermal Regime of an Arctic Lake

MAX C. BREWER

Abstract—Much of the Arctic coastal plain in Alaska is covered by shallow lakes. Those in the Barrow area, which are believed to be representative of most of the lakes in the coastal plain, are generally either two to three feet or six to nine feet deep. The shallow lakes can often provide a suitable summer water supply, but only the deeper lakes provide a significant water supply throughout the year.

The water in the individual lakes is in an essentially isothermal state during the ice-free period that lasts from late June until September. The maximum temperature recorded in a lake near Barrow in 1954 was about 12°C. When ice formation begins, the temperature of the body of water as a whole may be only a few tenths of a degree above 0°C. Once the lake surface is iced over, the water temperatures may rise rapidly as much as 2°C., apparently owing to radiated heat received through the ice. The heating is terminated by a sudden cooling that coincides with the covering of the ice by a thin blanket of snow. This cooling is followed in turn by a second warming of the bottom and near-bottom water that takes place gradually over a period of weeks. The bottom sediments beneath the lake are the source of heat. The magnitude of the second rise and the time during which it takes place depend on the distance from shore and the depth of water. A gradual cooling takes place during the balance of the winter. Permafrost underlies the shallow lakes but an unfrozen basin several hundred feet deep may extend beneath the deeper lakes.

Introduction—Lakes or drained lake basins may comprise locally from less than 25 pct to as much as 90 pct of the surface area of the Arctic coastal plain of Alaska [*Black* and *Barksdale*, 1949]. The lakes in the Barrow area (Fig. 1), which are believed to be representative except in areal extent of most lakes in the coastal plain, are either two or three feet or six to nine feet deep.

The lakes are important sources of water supply for the people in the area. Deep pockets in rivers can also provide an additional source of water in both winter and summer. Because of the considerable thickness of permafrost (as much as 1300 ft), no wells to date have provided usable water at Barrow, or have ever been drilled to my knowledge. *Cederstrom* [1952] has described limited supplies of ground water at Kotzebue and Point Hope but these places are south and west of the coastal plain and it is very doubtful that similar conditions would prevail near Barrow. The shallow lakes can often provide a limited suitable water supply during the summer but, once ice formation begins, the supply of water decreases rapidly and by midwinter they provide water only in the form of ice. Lakes more than six to seven feet deep do not freeze to bottom and can provide a limited water supply throughout the winter and a large supply in the summer.

The U.S. Geological Survey has studied the thermal regimes of several lakes in the Barrow and Umiat areas as part of a program of investigation of the distribution of and temperatures in permafrost in northern Alaska and because of the need for specific information on sources of water supply. Detailed studies were made from 1951 to 1955 in Fresh Lake (locally Imikpuk, which means 'big drinking water' in Eskimo). This lake is the nearest year-around source of fresh water to Barrow Camp which is situated on the ocean beach immediately west of the lake 3½ miles northeast of Barrow (Fig. 1).

Imikpuk Lake—Imikpuk Lake has an approximate area of 155 acres and at its closest point lies within about 400 ft of the Arctic Ocean (Fig. 2). The lake is elliptical in shape and its long dimension is approximately north-south. It can thus be considered typical of the lakes in this part of northern Alaska which generally have their long dimension oriented in a north-south direction [*Black* and *Barksdale*, 1949]. The deepest part of the basin, approximately ten feet, is west of the center of the Lake.

Imikpuk is separated from the ocean by a gravel beach with a maximum height of ten feet. This beach is normally sufficiently high to prevent any inrushing of ocean water during storms although some contamination did occur during an unusually severe storm in October 1954. The average water level of the lake is about two feet higher than that of the ocean; it had been assumed that the water remained fresh because the lake was separated from the ocean by a continuous impermeable

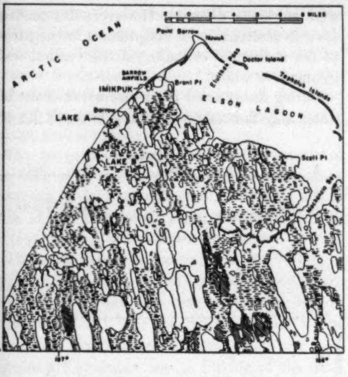

FIG. 1 – Numerous lakes and old lake basins dotting the Arctic coastal plain near Barrow, Alaska

permafrost barrier beneath the beach. Investigations by the U. S. Geological Survey indicate that there is a shallow frozen dam of varying thickness but that it does not extend to depths greater than 30 feet. There is in fact an unfrozen zone with a high saline content beneath the frozen beach gravels. This unfrozen zone is continuous with an unfrozen zone, also thought to have a high saline content, beneath the lake. It therefore seems that the fresh water in the lake is resting on brine-contaminated sediments whose pore water is not sealed off from the ocean. This condition should not endanger the existence of the lake as a source of fresh water, however; the only real danger to the use of the lake as a source of potable water, other than contamination by refuse, lies in the possibility that the ocean may breach the shallow permafrost dam during an unusually severe storm and that the lake will be converted to a lagoon. Several Barrow inhabitants say that one or two lagoons have been formed in this way within the last century and an interpretation of local geologic history suggests many others have had a similar history.

Techniques of observation—The measurements of the temperature in the lake during the winter were obtained by freezing multiconductor cables containing regularly spaced thermistors, [*Swartz*, 1954], into the ice and leaving these cables in place for periodic measurements through the season. Readings were usually obtained three times weekly although there were periods when readings were obtained at intervals as short as six hours or as infrequently as once a week. Tests based on the use of an ice-water bath for a standard indicate the accuracy for all measurements is better than 0.1°C, usually close to 0.03°C. The accuracy of the measurement of temperature change at any one thermistor is ±0.01°C.

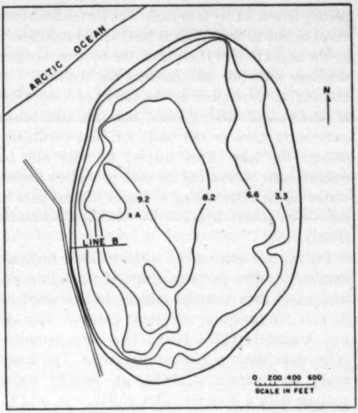

FIG. 2 – Bottom contours (in feet) of Imikpuk Lake near Barrow, Alaska [after *Comita*, 1953]

The measurements of the temperature of water during the summer were obtained by attaching multiconductor thermistor cables (painted white) to wooden poles that were shoved or driven into the lake-bottom mud and left in place. Some of these cables were left in place and frozen in an upright position for continued use during the winter.

A hole 200 ft deep (point A in Fig. 2) was drilled beneath the lake in the spring of 1953. Thermistor cables were installed and successfully read then and again late that fall.

A thermistor cable containing 27 regularly spaced thermistors was laid along the bottom of the lake from a point near shore to a point 546 ft from shore (line B in Fig. 2) in the fall of 1954. Periodic readings were obtained from this cable for a period of one year.

Temperatures during periods of open water—The ice in the lakes on the Alaskan coastal plain usually starts to melt during the first week of June. In the shallow lakes the ice may melt from the top without ever floating and the lakes may be completely free of ice by late June. The ice in the deeper lakes begins to float after it has melted sufficiently at the edges to free itself from the bottom. Surface drainage into the lake hastens the melting. The floating ice is subject to the forces of wind while it continues to melt; it often rams the lake banks sufficiently hard to roll back turf and eventually enlarge the lake. This floating ice may also be instrumental in creating the shelf or shallow underwater bench surrounding a deeper central part in lakes such as was described by *Black* and *Barksdale* [1949].

During the summers of 1951 to 1956 Imikpuk became ice free between July 17 and July 28. The water then warmed rapidly and attained its highest temperature sometime between July 30 and August 14 (1952–1955). The water temperatures then began a fluctuating decline. The maximum temperature in 1954, an usually warm summer with a thawing index of 933, was +12°C. (The thawing index is defined as the total cumulative (degree F) days above freezing for a thawing season [*Linell*, 1953].) The maximum temperature during 1955, an unusually cold summer with a thawing index of 310, was +8°C. The average thawing index at Barrow is about 600.

The water in Imikpuk is essentially isothermal both vertically (Fig. 3) and horizontally (Fig. 4) at any time during the ice-free period. Some indication of vertical temperature stratification in the upper foot of water in the lake has been noted (August 11 and September 17, 1954 in Fig. 3) on days when the temperatures of the air and water were markedly different. However, this tendency towards stratification is insignificant in comparison to the isothermal character of the vertical water column as a whole.

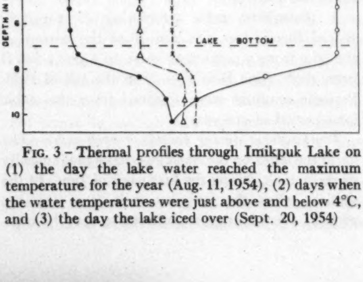

FIG. 3 – Thermal profiles through Imikpuk Lake on (1) the day the lake water reached the maximum temperature for the year (Aug. 11, 1954), (2) days when the water temperatures were just above and below 4°C, and (3) the day the lake iced over (Sept. 20, 1954)

During the summer the temperature of the lake water may fluctuate a degree or two per day and

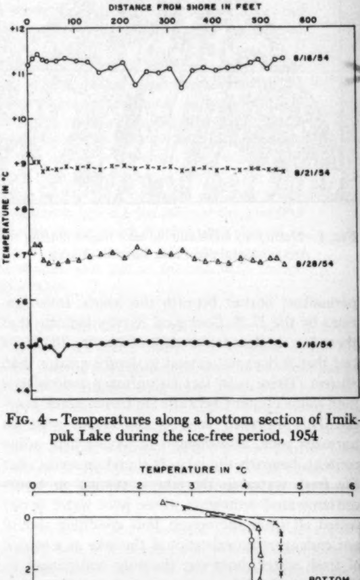

FIG. 4 – Temperatures along a bottom section of Imikpuk Lake during the ice-free period, 1954

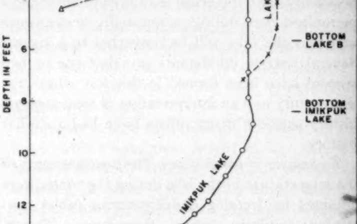

FIG. 5. – Thermal profiles through lakes of different depths near Barrow, Alaska, September 1, 1952

the fluctuation is always approximately the same for the entire column (see data for September 13, 17, and 20, 1954, Fig. 3) even though sometime between September 13 and 17 the water in the lake reached its maximum density and the direction of the thermal gradient in a stable water column was reversed.

The temperature of the mud in the bottom of the lake also fluctuates. However, there is a phase lag in the time of fluctuation and the amplitude of the fluctuation is rapidly damped with increasing depth beneath the lake bottom.

The temperature in the water on the bottom of Imikpuk is the same, within a few tenths of a degree Centigrade, at any one time during the ice-free period, (Fig. 4). The small irregularities in the horizontal temperature profiles along the lake bottom are probably due to sinking of the cable and the measuring elements into the mud, or to areas in which the bottom material has different radiative properties. As the vertical water column is also in an essentially isothermal state at any one time (as is verified by many sets of readings taken at several stations during the summers of 1951–1955), it has been concluded that the whole lake is in essentially an isothermal state at any given time during the ice-free period.

To determine if this isothermal condition prevailed in other lakes or was unique to Imikpuk, vertical thermal profiles through Imikpuk and two other lakes of different depths in the Barrow area were measured on September 1, 1952 (Fig. 5). Lake A and Imikpuk Lake are near the Arctic coast and probably subject to about the same weather conditions. Lake B, with a basin approximately the same depth as Imikpuk, is about six miles inland from the coast and should be less affected by the moderating influence of the ocean. Lake A is 2.6 feet deep and underlain by permafrost at a depth of less than five feet, whereas

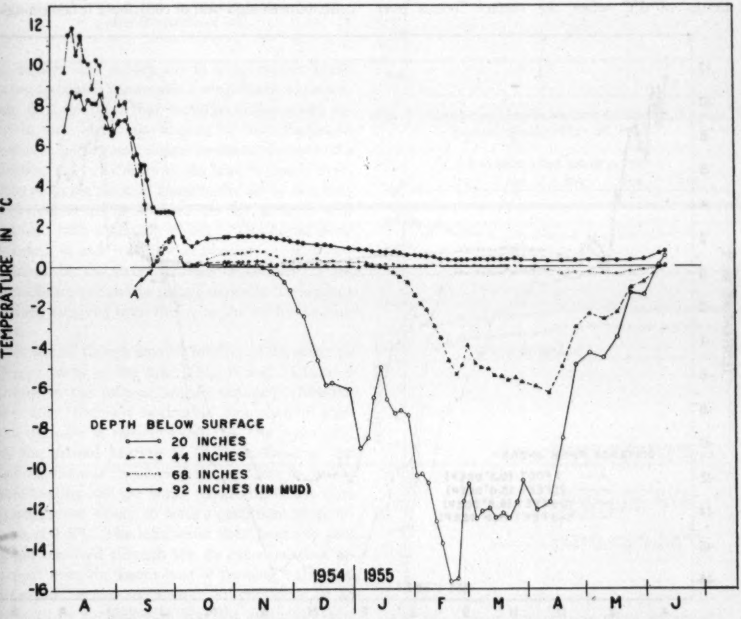

FIG. 6 – Time-temperature curves at several depths in Imikpuk Lake near Barrow, Alaska; lake 6 ft 4 in deep at this site

Imikpuk is 8.4 feet deep at the point of measurement and there is no permafrost within the first 190 ft under the deeper part of the lake. Despite these differences, the temperatures of the water in the three lakes were similar and each lake was in an isothermal state.

Temperatures during period of ice cover—A thin skin of ice may form on the fresh-water lakes in the Barrow area any time after September 1. The lakes usually ice over completely for the winter September 15–20 although open water remained until September 30 once during the six years of observation (1950–1955). As soon as the lake is iced over, freezing proceeds rapidly and the ice may be four to six inches thick within two weeks. Initially the ice freezes faster near shore giving the impression of an arch (possibly six inches at the edge and four inches 100 ft from shore) covering the water. However, as the winter progresses, the arch tends to disappear.

The temperature of the lake is within a few tenths of 0°C when the surface freezes over (September 20, Fig. 3). As soon as the lake is completely iced over the temperature of the water at all depths except near the freezing surface begins to increase rapidly (point A in Fig. 6). At the same time the temperature in the mud beneath the lake (Fig. 6, 92-inch depth) stops its rapid decrease and may remain virtually the same for approximately two weeks indicating a sharp decrease in the rate of heat loss from the sediments during this time. In the fall of 1954, the increase in the temperature of the lake was approximately 2°C. The maximum temperature was reached in 11 days (September 20 to October 1) and five days later the temperature returned to approximately that prevailing before the sudden rise. The rise seemed to be general throughout the lake. The possible sources of heat are the warmer sediments beneath the lake, bacterial action, or radiation. The warmer bottom sediments may contribute a minor amount of heat; however, the low thermal gradient and the length of time involved indicate that the sediments cannot contribute enough heat or contribute it fast enough

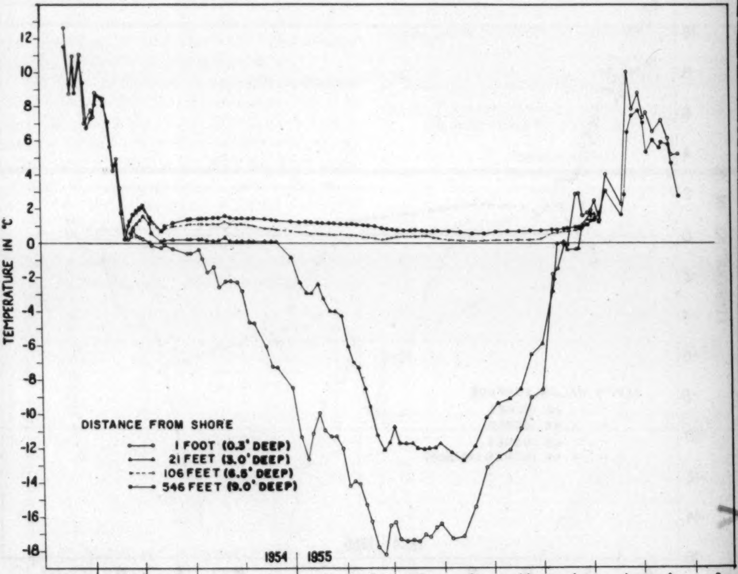

Fig. 7 – Time-temperature curves along bottom of Imikpuk Lake near Barrow, Alaska

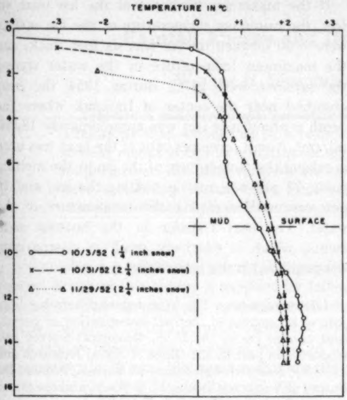

FIG. 8 – Thermal profiles through Imikpuk Lake showing second heating and cooling of bottom water after formation of ice

to explain this sudden rise in temperature. There is not too much known about weak bacterial action, but it is doubtful that bacterial action could account for a significant amount of heat. Radiation seems to be the most logical source of the heat; the heating starts as soon as the lake is frozen over, thus reducing the heat losses to the air by evaporation and stops as soon as the ice is fairly well covered with a blanket of snow. The initial snow blanket would reduce the amount of radiation received by the water through the ice and yet not be sufficiently thick to reduce radically the amount of heat escaping from the ice to the air by conduction.

A second though smaller heating of the water in deeper parts of the lake, (Fig. 6 and 7) from a source in the warmer bottom sediments beneath the lake, becomes noticeable immediately after the decrease in radiative heating. The magnitude of the second heating in Imikpuk Lake in the fall of 1954 was about one-half that from the radiative heating and the water required a longer time (about seven weeks) to reach a maximum temperature of 1.5°C. The lake water then began to cool (heat removed through the ice exceeded that received from the latent heat of freezing water and from the bottom sediments) and continued to do so until by the following May the maximum temperature in the lake was 0.6°C. During the latter period of heating and cooling the thermal profile through the water becomes a smooth continuous curve joining the temperature at the bottom of the ice with that in the bottom sediments (Fig. 8).

Prominent zero curtains are evident at depths of

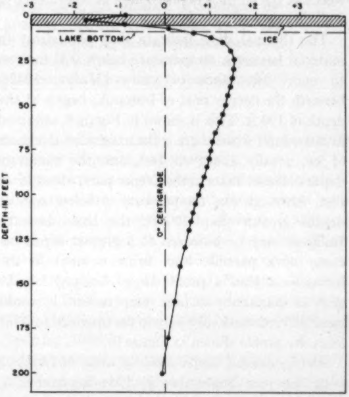

FIG. 9 – Geothermal profile beneath Imikpuk Lake near Barrow, Alaska, May 26, 1956

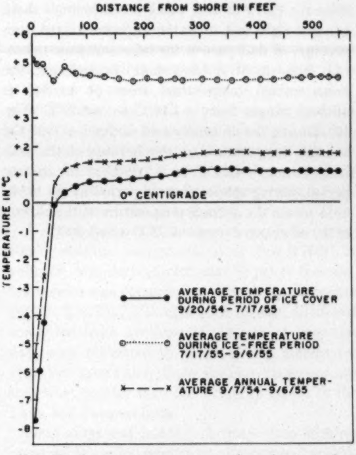

FIG. 10 – Average temperatures along bottom of Imikpuk Lake

20, 44, and 68 inches (Fig. 6) and at 21 feet from shore (Fig. 7). (The zero curtain is an interval of time during which the temperature remains constant as the chilling of water is temporarily compensated for by the latent heat of fusion [*Muller*, 1947].) The zero curtain persists for almost 10 weeks at the 68-inch depth. There is no evidence of a similar zero curtain in the spring (Fig. 7).

The thermal data indicate that permafrost (a material having a temperature below 0°C for two to many thousands of years [*Muller*, 1947]) beneath the deeper part of Imikpuk, begins at the depth of 190 ft. This is shown in Figure 9, obtained in late winter when there is the maximum thickness of ice, usually about six feet, and the minimum depth of liquid water in the deeper part, about three feet. Although the temperature is below zero at depths greater than 190 ft, the basin beneath Imikpuk may be unfrozen to a greater depth because of a possible high brine content in the formations. Had a profile been obtained for the time of maximum surface temperature, it would have differed markedly only in the upper 20 to 30 ft from the profile shown in Figure 9.

Average annual temperatures of water at Imikpuk—In the year September 7, 1954–September 6, 1955 the mean annual temperature at the bottom of Imikpuk ranged from —5.48°C at a point one foot from shore where the water was four inches deep to +1.79°C at a point 356 feet from shore beneath eight feet of water. However, if the temperature of that part of the lake that froze to bottom (edge to 61 ft from shore) is neglected, the mean annual temperature from 61 to 546 ft offshore ranges from +1.18°C to +1.79°C (Fig. 10). During the unusually cold summer of 1955 the average temperature at the bottom of the lake ranged from +4.29°C to +5.05°C in the ice-free period; during the ice-covered period in the 1954–1955 season the average temperature at the bottom of the lake ranged from —7.75°C to +1.20°C.

If the maximum thickness of the ice were six feet, the minimum temperature of the ice surface were —30°C when the ice was six feet thick, and the maximum temperature of the water during the summer were 12°C, during 1954 the heat absorbed near the center of Imikpuk where the depth is about nine feet was approximately 18,000 cal/cm². About seven per cent of the heat was used in raising the temperature of the ice to the melting point, 75 pct was used in melting the ice, and 18 pct was used in raising the temperature of the water. The heat transfer in the bottom sediments, which is relatively small in comparison, was neglected in this calculation.

Acknowledgments—The work reported here has been part of a program of thermal investigation of permafrost carried on by the U. S. Geological Survey and supported in part by the Office of Naval Research and its Arctic Research Laboratory at Barrow, Alaska, the Bureau of Yards and Docks, U. S. Navy, and the Snow, Ice and Permafrost Research Establishment, Corps of Engineers, U. S. Army.

Rainfall Energy and Its Relationship to Soil Loss

WALTER H. WISCHMEIER AND DWIGHT D. SMITH

Abstract—A relatively simple procedure is presented for computation of kinetic energy of a rainstorm from information on a recording-raingage chart. An equation is developed describing rainfall energy as a function of rainfall intensity. The effects of rainfall energy and its interaction with other variables are evaluated in multiple regression analyses based on data representing four soil types. Application of this information to separate the effects of rainfall from those of physical and management characteristics in plot data is discussed briefly.

Soil erosion is a mechanical process that requires energy. Much of this energy is supplied by falling raindrops. The tremendous magnitude of the kinetic energy of rainfall is readily apparent from a few simple calculations. The dead weight of the water falling in 30 min. of a common thunderstorm in the cornbelt states may well exceed 100 tons on each acre. The billions of drops which comprise this 100-ton volume of water strike the soil, if unprotected, at an average velocity of nearly 20 mi/hr. The rainfall energy to be expended during the 30 minutes may well exceed two million foot-pounds per acre. If the rain is driven by violent winds, the energy of impact may be even greater.

In 1954, the Soil and Water Conservation Research Division of the Agricultural Research Service initiated a program to summarize all available runoff and soil-loss data on a national basis for further analyses. Studies on the project have pointed out that the accuracy of soil-loss prediction equations on an individual storm basis is considerably enhanced when a measure of rainfall energy is included as a variable, and that both the efficiency and the simplicity of such equations are further improved by terms measuring the interaction effects between variables. In this paper, a relatively simple procedure for computation of the approximate rainfall-energy value of a storm is presented, and the application of this information in more efficient estimates of expected soil loss is discussed.

Drop size—Studies of drop-size distribution of natural rainfall have shown a high degree of correlation between drop size and rainfall intensity. Size distributions of raindrops as a per cent of total volume were published by *Laws* and *Parsons* [1943] for intensities ranging from 0.01 to 6.0 inches per hour. These data are briefly summarized in Figure 1. The mean drop sizes, weighted by per cent of total volume, lie along the solid-line curve. The broken lines in the graph represent the boundaries of the 25–75 percentile and the 5–95 percentile ranges of drop size, respectively.

Measurements of raindrop records made on dyed filter papers for correlation with radar echoes were analyzed by *Marshall* and *Palmer* [1948] to give the distribution of drops by size. These distributions were in general agreement with those reported by Laws and Parsons. Information on raindrop size has also been reported by *Atlas* [1953], *Chapman* [1948], *Horton* [1948] and *Spilhaus* [1948b].

It is not expected that drops in sudden bursts of rain from a small cloud, or rains which are stopping and starting, would conform to any general size-distribution pattern. Data on the number of drops per unit volume for different types of rain indicate that the average volume per drop for a sudden rain from a small cloud or for the beginning of a short fall may be several times that in a general rain or a period of heavy continuous fall. This introduces a serious limitation to estimation of rainfall energy for such storms on the basis of intensity. Applied to rains of this type, soil loss prediction equations will, therefore, be less accurate. Fortunately, however, soil losses resulting from such storms generally comprise only a very small portion of the annual total.

A comprehensive summary of available drop-size information was presented by *Best* [1950a]. A value D_{50} was derived such that 50 pct of the rainfall volume was comprised of drops with diameters greater than D_{50}. Values of such median diameters computed from averages of six sets of drop-size data were tabulated by *Ekern* [1950]. Except for very low intensities, these median diameters are somewhat greater than the weighted means of the Laws and Parsons data.

Drop shape and velocity—A water drop with no appreciable motion relative to air assumes a spherical shape. However, a falling drop is deformed by flattening on the bottom and spreading sideways

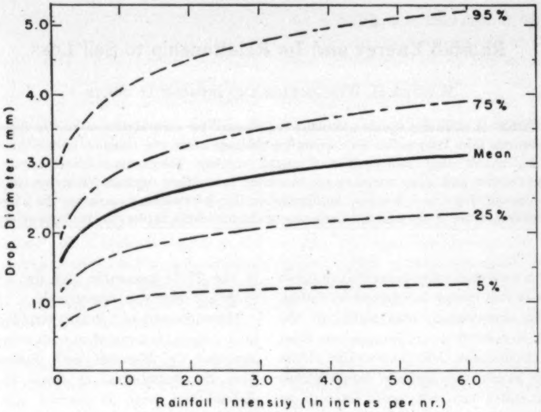

FIG. 1 – Drop-size distribution of natural rainfall

because of atmospheric pressure deficits developed on its top and sides and excess of pressure on the bottom. Terminal velocity is attained when the gravitational force on the drop is balanced by the drag of the air through which it is falling. Drops have been found to pass through a series of oscillations in shape while attaining terminal velocity. It does not appear unlikely that in simulated rain with a short fall, these oscillations may have a measurable effect on the stresses at impact. However, drops at their terminal velocity will usually have become stabilized in shape.

Published material on the terminal velocity of water drops includes reports by *Best* [1950b], *Blanchard* [1950], *Gunn* and *Kinzer* [1949], *Laws* [1941], and *Spilhaus* [1948a]. Gunn and Kinzer measured the terminal velocity of water droplets in stagnant air by inducing an electric charge and producing pulses on an oscillograph record. Their measurements are in good general agreement with values reported by Laws in 1941. Terminal velocities of drops of various sizes are plotted in figure 2, where equivalent drop diameter is defined as the diameter of a sphere of equivalent volume.

Rainfall energy table—If rainfall energy measurements are to be used extensively as a basis for more accurate estimation of rainfall erosion, a simple procedure for determining the kinetic energy of a rainstorm is required. Table 1 is presented to meet this need. Kinetic energies in foot tons per acre inch for natural rainfall at the various commonly experienced intensities have been tabulated.

The change in velocity corresponding to a one-unit change in drop diameter is much greater for the small drops than for the larger ones (see Fig. 2). Therefore, the mass and velocity of the median drop size substituted into the standard formula for

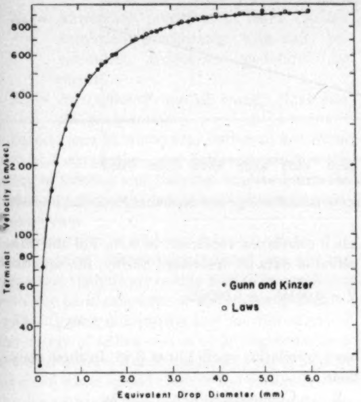

FIG. 2 – Terminal velocities of water-drops of different sizes in stagnant air

kinetic energy would yield results greater than the true energy value. The regression equation from which the values in Table 1 were derived is

$$Y = 916 + 331 \log_{10}X$$

where Y is the kinetic energy in foot tons per acre inch, and X is the rainfall intensity in inches per hour.

The equation is based upon the detailed drop size distribution data published by *Laws* and *Parsons* and the published terminal velocities plotted in Figure 2. It is an excellent least-squares fit to the data. Energy values in Table 1 for intensities greater than six inches per hour were extrapolated. In view of the clear trends in the terminal velocity and drop size distribution data, such extrapolation beyond the range of the data appears sound.

To compute the energy value of a rainstorm, Table 1 is used with the information available from a recording raingage chart. A tabular record of intensities, with the amount of rain falling at each of the successive intensity increments, is obtained from the recorder chart. The table is entered with the midvalue of a specific intensity increment. The corresponding energy figure from the table multiplied by the inches of rain falling at this rate describes the energy value of that increment of the storm. These partial products are accumulated in a desk calculator to obtain the total energy value for the storm. Intensity intervals should not be large enough to average widely differing rainfall rates. Such average intensities would result in low computed values of kinetic energy.

Evaluation of the effects of rainfall characteristics—It is apparent to the observer that two rainstorms of equal total amount falling on the same field and on comparable surface conditions often produce widely differing soil losses. In order to analyze and solve erosion problems, it is necessary to know which characteristics of rainfall are responsible for such differences, and how and to what extent erosion is affected by each. This problem was approached primarily on a mathematical basis through multiple correlation analysis.

A large number of runoff and soil-loss data on an individual storm basis are available from plots in continuous fallow, with cultural operations identical to those on the corn plots, and kept free of vegetal cover throughout the period of study. These data lend themselves to a study of rainfall effects undisturbed by differences in cover, amounts of organic matter in the soil, or other management practices. Availability of an electronic digital computer for the studies made it possible to compute multiple regression equations of soil loss on as many as 19 variables, simultaneously. Special emphasis was directed toward evaluation of effects of interactions of the variables. Data employed in the studies were from several major soil types and included variations in precipitation patterns. The coefficient of determination, which is the percent of total storm-to-storm variation in soil loss explained by the particular factor, was used as a measure of the degree of influence of that factor on soil loss.

The absolute values of the effects of the various rainfall characteristics vary with soil type and slope. However, the relative rank of the specific factors does not appear to differ for the soils and slopes included in the study.

Numerous combinations of rainfall characteristics, interaction effects, and indices of antecedent moisture and soil compaction were investigated in exploratory studies. The best single variable found for prediction of soil loss from cultivated fallow soil is the product of the total rainfall energy of a storm and its maximum 30-minute intensity. This product term measures the interaction effect of the two rainfall characteristics. It will be referred to hereafter as the $E \times I$ variable.

The regression line is plotted in Figure 3 for a

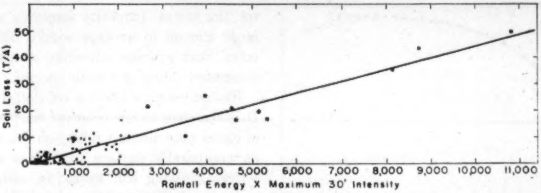

FIG. 3 – Individual-storm soil loss is a function of the product of rainfall energy and maximum 30-minute intensity

ten-year record, exclusive of the rough-plow winter period, on Shelby soil with a slope of eight per cent. The unit of the $E \times I$ variable on the horizontal axis is energy in foot-tons per acre-inch times maximum 30-minute intensity in inches per hour. Rains of a half inch or more, and smaller rains which resulted in measurable runoff, were included in the analysis. The solid block at the origin represents 60 observations. It is apparent that points representing storms with negligible soil losses were successfully concentrated near the origin when related to the $E \times I$ variable. The analysis indicates 95-pct confidence that the slope of the true regression line lies within the narrow band of 0.0042 to 0.0047.

In each of the five sets of data analyzed, the single $E \times I$ variable accounted for a greater portion of the total soil-loss variation than did a multiple regression on the five variables: rainfall amount, maximum 5-, 15- and 30-minute intensities, and antecedent precipitation. Mathematically, this very highly significant interaction of rainfall energy with maximum intensity means that the rainfall energy-soil loss relationship for a storm with any specific maximum 30-minute intensity is quite different from the energy-soil loss relationship for a storm with some other 30-minute intensity level. The values of some of the significant terms and combinations as soil-loss predictors are compared in Table 2.

The $E \times I$ interaction term is outstanding as a common denominator for rainstorm classification on the basis of erosion-producing capacity. Little, if any, accuracy is added by including rainstorm characteristics other than total energy in the equation. Efficiency of the prediction equation is improved, however, by the additions of rainfall energy and indices of soil moisture and compaction. For ten years of Shelby data exclusive of the winter period, the equation

$$Y = 0.00163X_e + 0.00389X_i + 0.0622X_a + 0.438X_p - 2.46$$

has a correlation coefficient of 0.96. For the same period of data on desurfaced Shelby, the equation

$$Y = 0.0026X_e + 0.0024X_i + 0.0517_a + 0.2330X_p - 2.93$$

has a correlation coefficient of 0.93. In these equations

Y = Computed soil loss, tons/ac
X_e = Kinetic energy of the rain in foot tons/ac.
X_i = $E \times I$

TABLE 2 – *Per cent of total storm-to-storm variation in soil loss explained (R^2) by the designated variables in regression equations*

Variables in regression equation	Soil type and number of storms in analysis[a]					
	Shelby[b] 138		Shelby 207	Shelby subsoil[c] 207	Marshall subsoil[c] 131	Fayette 144
	σ^d	R^2	R^2	R^2	R^2	R^2
Rainfall amount	4.0	73.0	68.3	64.6	38.7	42.2
Rainfall energy	3.3	81.7	78.2	73.9	54.9	61.6
Max 15-min intensity	5.8	43.4	40.9	25.7	50.4	65.5
Max 30-min intensity	5.1	56.2	59.8	35.1	56.0	79.9
Three variables[e]	3.6	78.6	73.8	67.6	66.2	82.6
$E \times I$ alone	2.5	89.2	81.7	75.6	70.7	88.0
$E \times I$ with 3 others[f]	2.2	92.1	85.8	80.2	78.6	88.3

[a] Shelby data include 10 yr of record on 8 pct slope; Marshall, 7 yr on 9 pct slope; Fayette, 6 yr on 16 pct slope.

[b] Shelby plots were fall plowed. The 138 storms exclude the rough-plow winter period. Other four groups include data for entire year.

[c] Seven inches topsoil mechanically removed.

[d] Standard error of estimate for the 138 storms in first R^2 column.

[e] Rainfall amount, max 15-min intensity and max 30-min intensity combined in multiple regression.

[f] Rainfall energy, $E \times I$, antecedent precipitation index, and total rainfall energy since last tillage operation.

X_p = Antecedent precipitation index (30-day antecedent precipitation with daily between-rain reductions modulated by season).

X_e = Accumulated rainfall energy since last tillage operation.

Inaccuracies in wintertime indices of soil moisture and compaction, and failure to measure the effect of freezing and thawing, tend to lower the estimating efficiency of an equation based on year-around data.

Interpretation of mathematical relationships—The mathematical relationships pointed out by the regression analysis are readily seen to be consistent with the basic principles of the erosion process.

The erosive actions of water are the effects of the energy of falling rain or of flowing water over the land surface. Runoff takes the form of shallow layers of water spread more or less uniformly over the land surface, and of channelized flow concentrated into defined watercourses. The former, coupled with raindrop action, produces sheet erosion. The concentrated scouring action of the channelized flow causes rill and gully erosion.

Sheet erosion is a function of rainfall characteristics, although the magnitude of the effects varies with soil condition, slope, cover, and management practices. It involves detachment of soil particles and transportation of the detached particles from the plot or field. Much of the raindrop energy may be expended in puddling and sealing of the land surface and in direct compaction of the soil. This results in increased runoff and intensification of rill erosion.

Splash erosion occurs whenever raindrops of sufficient size strike moist, unprotected soil as photographed in Figure 4. This results in a leveling of the surface and, on sloping land, in a gradual movement of surface particles down the slope. This type of erosion is not immediately measured, but may influence the amount of soil removed from the plot by a subsequent runoff.

When rainfall intensity exceeds the infiltration rate plus surface detention, excess water moves downhill, thus providing transportation for many of the detached soil particles that would not otherwise move off the plot. The velocity attained by the flowing water is a function of its depth and amount of vertical fall. Its silt-carrying capacity increases exponentially with the increasing velocity. Not only soil detached by the raindrops, but also additional soil detached by the flowing water, is carried from the field in increasing amounts as the depth of flow increases.

FIG. 4 – A raindrop striking moist soil bursts upwards and outwards, carrying pieces of soil with it (USDA-SCS photo by U. S. Navy Bureau Yards & Docks, Nov. 1949)

Depths attained by sheet flow under normal field conditions usually do not exceed a small fraction of an inch. The energy imparted by raindrop impact contributes greatly to erosion by such shallow flows. The direct splash action is reduced, but the energies of the falling drops are transferred to the surface flow in the form of turbulence and help to detach soil and to hold detached materials in suspension.

The $E \times I$ interaction variable appears to be a good measure of the combined effects of (a) the decreasing infiltration rate during a rain, (b) the geometrically increasing erosion effect of surface flow, and (c) the protection against raindrop splash which is afforded by the film of flowing water. A storm with rainfall energy per acre equivalent to that of an average rain but with very low maximum intensity would have an $E \times I$ value low enough to predict no soil loss in spite of the energy value. If the low-intensity rain lasts long enough, the infiltration rate may finally become low enough for runoff to occur. This would show up in the prediction equation by a sufficiently increased total rainfall energy to make the $E \times I$ product term large enough to predict soil loss. Another rain, with much smaller amount and total energy than the one just described but falling at a high intensity, may produce a comparable soil loss. Similarly, the magnitude of the product of a low energy value and a high intensity may be comparable to that of one with high energy and low intensity. In the case of a large rain at high intensity, the increased soil-detaching and soil-carrying capacities of the turbulent flow are described by the very large product of the two high components of the $E \times I$ term.

The interaction of energy with 15-minute maximum intensity is also highly correlated with soil loss but not so highly as the interaction with the 30-minute intensity.

The antecedent precipitation index in the equations affords a measure of the starting point on the time-infiltration rate curve.

The fourth variable in the equation, total rainfall energy since last cultivation, provides a measure of the effects of soil compaction, reduction in surface detention due to leveling of the surface by splash erosion, and sealing of the land surface.

An important part of the soil-loss variation not explained by the four variables in the erosion equation previously described is probably the result of wind effects. Increases in energy of impact due to driving winds were not included in the rainfall energy table. They probably account for some of the underestimated soil losses. Wind direction relative to the direction of land slope could affect the accuracy of soil loss prediction in two ways. In the first place, the detaching ability of the rain drops would be influenced by the angle of impact. Secondly, for a specific rain intensity measured in a vertical raingage, the energy of impact per unit area of land surface would not be the same for a rain driven by the wind in the direction of a rather steep land slope as for a similar rain in the opposite direction. Changes in wind direction during a rain probably tend to balance out these effects in many storms. However, when a strong wind holds a constant direction throughout the period of rain, deviation in actual rainfall energy from the computed amount could have a significant effect on soil loss. Related wind data are not available to test the importance of these hypotheses.

Applications of rainfall energy information—The preceding analyses indicate that, with factors other than rainfall held constant, soil loss per unit area from an individual storm varies as the product of rainfall energy and maximum 30-minute intensity. This fact has several valuable applications.

The ability to predict soil loss is improved by this more efficient measure of the effect of rainfall characteristics. The cost of computing multiple regression equations is gratifyingly reduced by the fact that one variable affords more information than four or five independent variables which would otherwise need to be included in the equation.

The accurate classification of rainstorms according to their soil-eroding potential is greatly facilitated by these findings. This will be a very convenient tool in analysis of accumulated data for the effects of slope, cover, and management effects.

Accurate evaluation of the erosivity of different soils has long been a problem to the application conservationist. The problem has been intensified by the fact that soil-loss data recorded at widely different locations had to be combined in efforts to evaluate these factors. Soil effects were confounded with the effects of differences in rainfall. It will now be possible to separate these effects and to add the rainfall factor to the slope-practice technique of applying conservation practices to the land. This will materially improve the accuracy of the method.

Some of the factors in current use for desribing cover and management effects are based on seriously limited available data. These can now be evaluated with greater confidence by considering the severity of the storms experienced in the brief periods of measurement as compared with long-run expectations.

Better measures of rainfall effects and soil-erodibility factors, used with soil classification data and Weather Bureau records, will increase the accuracy and degree of confidence with which research data may be adapted to other localities.

Some Methods of Alleviating Surface Clogging in Water Spreading with Emphasis on Filters

LEONARD SCHIFF AND CURTIS E. JOHNSON

Abstract—Methods of preventing or alleviating clogging of soil pores when spreading water on soil surfaces or injecting water into aquifers for recharge are discussed. Observations of methods such as suction cleaning or scraping to remove clogging materials and restore the infiltration rate in some installed systems are pointed out. Certain past experimental work on the subject is reviewed.

Of various filter materials used in infiltrometers at Bakersfield, sand ranging in size from 0.5 to 1.6 mm maintained a higher infiltration rate than ⅛ or ¼ inch pea gravel or the existing aquifer material. Information is given on particle size distribution of both the filter and aquifer materials. Head losses due to filters and within the underlying aquifer are shown.

Introduction—Artificial ground-water recharge is accomplished by spreading water over land surfaces or injecting water into aquifers through shafts, wells, pits, or trenches. The permeability of the soil surface and subsurface soil down to the ground-water table controls the rate of recharge. The permeability of soil varies with texture and structure of the soil, being greater for coarse textural classes and better soil structure. Organic matter contained in the soil and vegetative cover affect soil structure and amount and size of pores, particularly in the fine- to medium-textured soils.

Research in ground-water recharge is concerned with soil and water treatments which increase the size of and stabilize the soil pores. It is concerned also with preventing or alleviating clogging of pores which can take place during recharge. By increasing the rate of infiltration, more water can be added to the ground-water reservoir in a given time or the area required for recharge can be reduced. Spreading on smaller areas provides better control in replenishing subsurface waters where desired.

Swelling of soil colloids with wetting is inherent in soils and depends largely on the amount and kind of colloidal material. Clogging caused by soil slaking and dispersion can be a result of unstable structure of the soil. This condition often occurs in soils of low organic-matter content. Low permeability caused by dispersion and loss of structure is a characteristic of soils having a high exchangeable sodium percentage. This may be due to existing conditions or may be a result of spreading waters of high sodium percentage. Some dispersion and break-down of surface soil structure can be caused by the physical force of the water as it is spread over the soil surface. Soil clogging may occur also due to microbial activity and the resulting accumulation of slimes, gums, gases, and microbial tissue within the soil pores.

This paper deals expressly with clogging of the soil surface which results from deposition of silt and smaller size particles carried into the area with the spreading water. These soil deposits accumulate more rapidly when water is injected for recharge since large quantities of water are passed through a relatively small area as compared to surface spreading.

Previous work—*Mitchelson* and *Muckel* [1937] have shown the value of selecting the upper portions of alluvial fans for spreading as represented by the debris cones at the mouths of canyons in Southern California. Coarse-textured soils on such locations have high permeability. Flows laden heavily with sediment have been bypassed to prevent severe reduction in infiltration rate due to surface clogging. Early observations indicated recovery in infiltration rate when a drying period followed a wetting period during which some sediment was deposited.

Richter [1955] shows that infiltration rates are lower on finer textured soils than on the coarser textured ones on spreading areas in California. The average infiltration rate for a water-spreading season of several months ranges from 4.2 ft/day for a coarse-textured soil to 0.46 ft/day for a fine-textured soil. However, infiltration rates averaging 3.6 ft/day have been maintained for seasons of several months over a period of several years on a fine sandy loam with a good native cover at the Saticoy Spreading Grounds, Ventura County, California. The grass cover at Saticoy maintains an open, friable surface soil of good structure even though water with a turbidity up to 575 ppm of sediment is spread. Water is bypassed when it exceeds this turbidity. Observations by the Los

Angeles County Flood Control District indicate that routing water through settling basins prior to spreading to remove some sediment and growing native vegetation in spreading basins to deposit sediment have increased infiltration rates.

Schiff [1955] has observed that soil treatments with vegetation, organic matter, and chemicals resisted clogging in that order. Percolation rates of less pervious subsurface layers appeared to limit further increases in infiltration rate. High injection rates are maintained in wells along the coast at Manhattan Beach in Southern California by using chlorinated water, free from suspended solids. Chlorine is used to prevent sealing by microbial activity. The high cost of clear chlorinated water can be justified in this case since the system of injection wells protects an inland ground water basin from sea-water intrusion.

Because limiting subsurface layers exist in various areas, injection methods employing shafts, pits, and trenches have been investigated. Surface and subsurface soil layers of low permeability have been removed, which permitted high heads of water to contact aquifers of high permeability. *Schiff* [1956] has shown that infiltration rates as high as 60 times that obtained by surface spreading have been achieved by injection methods. However, sediments brought in by the river water cause clogging and periodic cleaning is required. Sediment deposits are removed by scraping. Benefits from the water in any area must be weighed against costs of water, construction, maintenance and land.

Water delivered to basins on Long Island, New York has recharged ground water at a rate of 3 ft/day. Water meandering in canals over a portion of 80-acre Rohrer Island, Dayton, Ohio, has recharged ground water at a rate of 107 ac ft/day. At Bakersfield, California, a $\frac{1}{3}$-acre narrow trench infiltrated as much water over a comparable period of a few months as surface spreading on four acres of land.

Suter [1956] has shown that, at the $\frac{1}{7}$-acre Peoria Pit in Illinois, injection rates increased from an average daily volume of 3.2 to 9.5 ac ft/day when the sand filter over the aquifer was replaced with $\frac{1}{4}$ inch pea gravel. The filter has been effectively cleaned by suction.

A $\frac{1}{10}$-acre pit at Bakersfield was excavated through six feet of relatively impervious material (Fig. 1). This pit extended three feet into an 8-ft lens of coarse sand. It exposed $\frac{1}{20}$-acre of sand aquifer. Using river water, the injection rate dropped from a volume of 2 to 1.2 ac ft/day in 82 days. The $\frac{1}{4}$ inch pea-gravel filter was not effective, and clogging deposits on the sand aquifer beneath the filter on both the bottom and sides of the pit were removed by scraping with hand shovels to restore the infiltration rate. Mechanical analysis of a surface crust deposited in the pit showed that 81 pct of the material was clay.

Purpose of experiment—The remainder of this paper deals with an experiment to find filter materials that will sustain higher infiltration rates of aquifers. Apparently a filter material is needed that will cause sedimentation through a depth of the filter and thus retain sufficient porosity to sustain reasonably high infiltration rates during a spread-

FIG. 1 – Infiltration pit, Bakersfield, California, $\frac{1}{10}$-acre in area, which exposes $\frac{1}{20}$-acre of sand aquifer six feet beneath relatively impervious surface soil

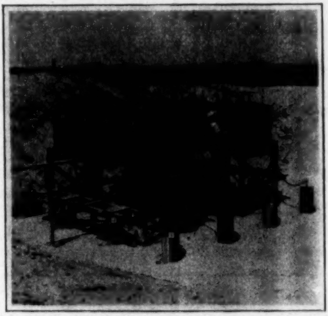

FIG. 2 – Arrangement of sixteen infiltrometers equipped with manometers to register head losses in filters and underlying aquifer material

ing season. The depth should be such as to permit cleaning by suction or by scraping at a reasonable cost. (The cheapest solution in some areas may be to inject water directly on an aquifer and clean by more frequent scraping than a filter may require.)

Procedure—Figure 2 shows 16 manometer-equipped infiltrometers with supply tanks located in a pit excavated to a depth of six feet to reach aquifer material. The aquifer material exposed is similar to the material in the 1/10-acre Bakersfield infiltration pit nearby, described above. The infiltrometers are three feet long and one foot in diameter. They were driven one foot into the aquifer material. Each infiltrometer is supplied with water from a storage drum. Surface head or depth of water in each infiltrometer is regulated by a float-controlled valve within the infiltrometer. The drums are supplied with water from a nearby ditch. There is a continuous supply of water to the infiltrometers at all times. Infiltration rate in a given infiltrometer is obtained by shutting off the water supply to the drum and measuring the rate of change of volume of water within the drum. The supply to the drum is turned on before the drum runs dry, thus maintaining a constant head of water within the infiltrometer. Kern River water is used for all runs. A run is considered to be a constant application of water over any period of time. Information is obtained on suspended solids and temperature of the water within the infiltrometers.

Filter materials 0.2 foot in depth were placed over the aquifer material. These materials included sand ranging in size from 0.5 to 1.6 mm, ⅛-inch pea gravel, and ¼-inch pea gravel (similar to the filter material used in the 1/10-acre pit).

Four infiltrometers containing aquifer material had no filters and are referred to as the controls. Table 1 shows a particle size analysis for the aquifer material for five depths at three locations. Table 2 shows a particle size analysis of all filtering materials.

Three runs were made. During the first and second runs, all filtering materials and the controls were replicated four times in a latin square design. During the third run, the sand filter and the con-

trol were replicated four times. For the first run, the filter material was washed and dried and placed within the infiltrometers to a depth of 0.2 foot. For the second run, all filter materials used in the first run along with the aquifer material to a depth of 0.2 ft were removed and discarded. The infiltrometers were then driven 0.2 ft deeper into the aquifer material, and washed and dried filter material was placed in infiltrometers to a depth of 0.2 ft. The first and second runs were identical in design. For the third run, the above procedure was followed except that sand filter material was placed in the four infiltrometers used as controls (no filters) during the first and second runs, and the four infiltrometers from which the sand filters had been removed were used as controls. This tended to eliminate the possibility that differences were due to location.

A surface head or depth of water of 1.9 ft was maintained on the surface of the aquifer material during all runs. Losses in hydraulic head at the bottom of each filter and 0.1, 0.2, and 0.4 foot beneath the surface of the aquifer material were determined with manometers (Fig. 3).

Results and discussion—Table 3 shows the effect of the different filter materials on the infiltration rate of the aquifer material. Statistical analysis showed that the variance due to location of infiltrometers (columns and rows in the latin square design) is similar and non-significant. Increases in infiltration rate with the sand filter compared to the aquifer material without a filter are significant at the five per cent level during the first and third runs and at the one per cent level during the second run. In all tests, the coarse sand was the most effective in sustaining increased infiltration rates, whereas the ⅛-inch pea gravel was significantly effective in only the second run, and the ¼-inch pea gravel gave no significant improvement.

Hydraulic head losses occurred in the sand filters during the first and second runs averaging 0.05 and 0.02 ft respectively. Measurable head loss did not occur in the ⅛-inch and ¼-inch pea gravels. Average hydraulic head losses, infiltration rates, and hydraulic conductivities occurring in the aquifer material within the 0–0.2 ft depth with no filter and with a sand filter during the third run are shown in Table 4.

The data indicate more rapid clogging occurred in the aquifer material which had no filter than in the aquifer provided with a sand filter. No pressure greater than atmospheric was recorded at the 0.2-ft aquifer depth after eight days of run on the aquifer without filter material. This showed that the maximum hydraulic head (2.1 ft due to position) had been lost. At this time, 1.44 ft of head had been lost in the aquifer covered by the sand filter, and the maximum head was not lost until the 19th day.

Table 5 shows suspended solids contained in the water in the infiltrometers on various dates. The large range in suspended solids is due to maintenance operations in canals and to storms

that vary considerably in intensity. Generally, turbidity is not high. However, there are periods during which suspended solids are high enough to cause clogging, particularly in injection spreading where the cumulative effect of the suspended solids becomes more rapidly detrimental than in surface spreading. Consequently, if suspended solids are not removed from the water prior to spreading, they must be removed by scraping or by filtering with subsequent cleaning of the filter by suction or by removal. The total amount and location of sediment and the size of particles are factors determining the frequency of cleaning.

[a] Water sampled when changes in turbidity were visibly apparent.

Table 6 shows the amount of fines in the 0–0.01 ft depth of aquifer material after a six-day run without filters compared to the fines initially present in the aquifer. During this time, turbidity of the supply water was low. Total fines less than 0.1 mm in diameter increased appreciably in the 0–0.01 ft depth, and a deposit was visibly apparent on the surface of the aquifer after the run. The data indicate that most of the deposit was composed of particles less than 0.002 mm in diameter. Previous analysis of deposits from the water on the surface of the nearby pit showed 81 pct of the material to be less than 0.002 mm in diameter.

Although the water temperature varied during runs and between runs, a check of individual infiltrometers showed that the water temperature did not vary appreciably between infiltrometers. Maximum temperatures varied from 24° to 38°C, minimum temperatures from 24° to 32°C, and mean temperatures from 26° to 30°C for the three runs.

Conclusions—The total infiltration through the aquifer material was nearly doubled or more than doubled when the sand filter was used as compared to the aquifer material with no filter. The filters of ⅛- and ¼-inch pea gravels were not particularly beneficial. The sand filter delays the sealing that normally takes place due to sedimentation in the aquifer material with no filter. Sedimentation and sealing of pores occurred more rapidly in the aquifer material under the ⅛- and ¼-inch pea gravel filters than under the sand filter. A filter is desired

Table 6 – *Amount of fines from 0 to 0.01 foot of aquifer material inherently and after a six-day run*

Infiltrometer	Fines in aquifer material for 0 to 0.01 foot depth								Total infiltration for six-day run
	Inherent				After six-day run				
	0.1–0.05mm	0.05–0.002mm	0.002mm	Total <0.1mm	0.1–0.05mm	0.05–0.002mm	0.002mm	Total <0.1mm	
	pct	pct	pct	pct	pct	pct	pct	pct	ft
1	1.2	0.3	1.0	2.5	2.7	2.1	4.5	9.3	93
6	1.9	0.3	2.1	4.3	1.4	0.3	3.4	5.1	127
13	0.3	0.1	1.5	1.9	0.8	0.2	2.6	3.6	116
16	0.1	0.1	1.1	1.3	0.4	0.3	2.3	3.0	123

that removes particles through a depth and not on a thin plane, thus maintaining permeability equal to or greater than the underlying aquifer material.

Another factor in maintaining higher infiltration rates seems to be the effect of the interface between the filter material and aquifer material beneath. Particle sizes for the sand filter and aquifer material are quite similar whereas the ⅛- and ¼-inch pea gravel filters are appreciably larger than the aquifer material. Similarity in size appears to establish a stable interface which probably is conducive to maintaining more rapid flow.

A filter material is desirable that will (1) filter out suspended solids through a depth, (2) stabilize the interface, and (3) not reduce effective pore openings of the material beneath.

Acknowledgments—Grateful acknowledgment is made to Herschel K. Kimble, Engineering Aide, for assistance in maintaining the filter experiment and for collecting data. The writers thank the Kern County Land Company for supplying land and water and for providing men and equipment to excavate and clean the Bakersfield experimental pit and trench.

Evapotranspiration Estimates from Heat-Budget Measurements over a Field Crop

V. E. SUOMI AND C. B. TANNER

Abstract—The heat-transfer processes which occur at the Earth's surface have direct bearing on many of the physical problems in agriculture that relate to the plant environment. The evapotranspiration from a crop can be estimated from the disposition of solar and sensible energy available at the earth-air interface. A suitable measurement of the heat budget, including net radiation, heat transfer by soil conduction, air-temperature gradient above the crop, and vapor pressure gradient above the crop, will account for the fraction of solar energy used hourly or daily for evapotranspiration. The simple theory, a brief description of the experimental equipment, and some illustrative measurements are discussed.

The importance of rainfall in agriculture is common knowledge. Equally important but not so obvious is the role of water loss. The moisture parameter of interest is really the difference of the two, that is, the soil moisture quantity, which can be measured directly by soil sampling. There are also indirect methods of obtaining soil moisture such as tensiometers and electrical conductivity block measurements. Aside from the disadvantage of the physical labor involved in obtaining the samples, the direct and indirect methods are likely to suffer from statistical error, unless a large number of measurements are taken. In addition it is difficult to transfer from values of tension or conductivity to volume of water per unit volume of the soil. (In this regard, the developments in soil-moisture measurement by means of neutron scattering are awaited with considerable interest. Here there appears to be a definite possibility of rapid sampling and good accuracy.) The purpose of this paper is to illustrate how the water loss at the Earth's surface can be estimated to good accuracy from the disposition of energy at the earth-air interface.

List of symbols—The following symbols are used.

R_n	net radiation
A	sensible heat flux (heating air)
S	soil heat flux
E	latent heat flux (evaporation)
β	Bowen ratio = A/E
L	latent heat of evaporation at plant temperature
ρ	air density
C_p	specific heat of moist air at constant pressure
T	air temperature, °C
∇_H	$\partial/\partial x + \partial/\partial y$
P	air pressure, *mb*
K_H	eddy coefficient of heat conductivity
K_w	eddy coefficient of vapor diffusivity
e	vapor pressure, *mb*
u	horizontal wind speed
ϵ	ratio of mole weights of water to air
R	specific gas constant
C	specific heat of the crop
ρ_c	density of the crop
Δ	finite increment

The heat budget—The heat budget of a volume the bottom face of which is the Earth's surface as shown in Figure 1 is, neglecting fractional heating

$$R_n + S + A + E + \int_0^z C_p \nabla_H (\rho ut)\, \delta z + \int_0^z \frac{L\epsilon}{R} \nabla_H \left(\frac{ue}{T}\right) \delta z + \int_0^z C\rho_c \frac{\partial T}{\partial t}\, \delta z + \int_0^z C_p\rho \frac{\partial T}{\partial t}\, \delta z + \int_0^z \frac{L\epsilon}{RT} \frac{\partial e}{\partial t}\, \delta z = 0 \qquad (1)$$

The first four terms represent the vertical heat (flux positive when flow is toward the volume) and the next two terms are the horizontal divergence of sensible and latent heat respectively. The last three terms represent the changes in sensible and latent heat stored in the volume. The change in the temperature of the crop and of the air are the sensible heat terms and the change of water vapor in the volume is the latent heat term. As $\delta z \rightarrow 0$, (1) reduces to

$$R_n + S + A + E = 0 \qquad (2)$$

This is the expression used by *Albrecht* [1943], *Sverdrup* [1936] and others. Since $\delta z > 0$ when vegetation covers the surface and measurements are made above the surface, it is necessary to evaluate the magnitude of the additional terms in (1).

Rider and *Robinson* [1951] have shown that the last two terms in (1) are only a small fraction of A and E during a clear day. They might be as

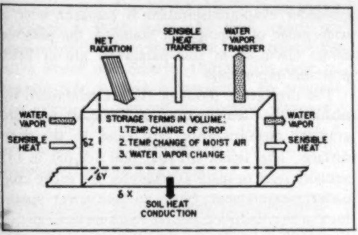

FIG. 1 - Schematic heat budget over a crop

large as ten per cent of A and E near sunrise and sunset or at night when $\partial T/\partial t$ is large and A and E at those hours are small. The heat stored in the crop is also negligible. Even when the crop is a heavy stand of corn, three meters high which yields 17 tons of silage to the acre, this heat is at most only one per cent of the total heat budget. Evidently during the day the storage terms can be ignored without introducing any appreciable error.

The divergence terms on the other hand may be large and to ignore them will introduce a large error. *Suomi* [1953] has shown, for example, that when measurements were made one to three meters above a crop of corn 2.5 m high, the divergence term can add as much as 40 pct to the evapotranspiration over that which would be obtained by (2). The divergence and storage terms can be minimized by taking the measurements near the surface so $\delta z \rightarrow 0$. We can test the validity of the assumptions used in the heat budget method by comparing its results against a more direct evapotranspiration measurement such as obtained with a lysimeter.

A properly exposed lysimeter will measure the total evapotranspiration as expressed in (1). The lysimeter used in this study has already been described *King, Tanner, Suomi* [1956]. A lysimeter, however, is not an absolute device. Its calibration depends on its area and its representativeness as well (sampling errors). While its tank area is easy enough to measure, the effective evapotranspiration area cannot be measured directly. Even though the lysimeter is not an absolute device, it still can be used for a test of heat budget evapotranspiration estimate. Ignoring for the moment the calibration of the instruments used for the heat budget measurement, if the ratio of the lysimeter evapotranspiration and the heat budget evapotranspiration is constant over a wide variety of weather conditions we will have demonstrated the reliability of the heat budget evaporation estimate. Stated differently this means that, provided the R_n and S terms are measured accurately, the partition of the residue into sensible heat flux and evapotranspiration is the same for both the heat budget and the lysimeter.

Calibration of the net radiometer and the soil heat flux instruments must be done independently. In this experiment, the net radiation is the largest term and is measured most accurately.

Instruments for heat-budget measurement—A schematic diagram of the instrument set up is shown in Figure 2. The divergence and storage terms in (1) are held to a low value by making the necessary measurements as near to the surface as possible. Measurements of net radiation R_n obtained with a net radiometer described by *Gier* and *Dunkle* [1951] or an improved model given by *Suomi* and others [1954] must be made one to three meters above the surface in order to keep the instrument's shadow from interfering with the measurement.

The soil heat conduction term S for the upper 10 cm of the soil is obtained from calorimetry *in situ*. Since the plant cover is highly variable, 12 thermometers, each of which measures the mean temperature change in a 10-cm column, are suitably placed to give the mean temperature change of the upper 10 cm of soil. The remaining soil heat flow below the 10-cm level is obtained with a heat meter [*Deacon*, 1950]. The heat meter, while very convenient, should not be used right at the soil surface because it interferes with moisture flow and subsequently the normal heat flow, and because a heat plate near the soil surface will be markedly influenced by the plant cover which may not be representative. The remaining sensible and latent heat transfer terms can be separated using the *Bowen* [1926] equation of the form

$$\beta = \frac{A}{E} = \frac{PC_pK_H\,\overline{(\partial T/\partial z)}}{L_eK_w\,\overline{(\partial e/\partial z)}} \tag{3}$$

Since the shape of the vertical moisture profile has approximately the same functional form as the vertical temperature gradient we can write $\left(\frac{\partial T/\partial z}{\partial e/\partial z}\right) \doteq \frac{\Delta T}{\Delta e}$. If we assume that $K_H = K_w$ the (3) reduces to

$$\beta = \left[\frac{C_pP}{L_e}\right]\left[\frac{\Delta T}{\Delta e}\right] \tag{4}$$

and we can obtain β by measuring the temperature and vapor pressure difference at two heights. There is considerable controversy regarding the equality of K_H and K_w. Some writers state that K_H/K_w is greater than unity during unstable stratification in the surface layer and less than unity with stable stratification. Others state that K_H/K_w should be set equal to the ratio of molecular diffusivities for air and water vapor or about 1.14. We see that β enters the expression for the solution of E in the form

$$-E = \frac{R_n + S}{1 + \beta} \qquad (5)$$

Thus the error in E will always be significantly less than the possible error in β due to an incorrect assumption concerning K_H and K_w. During conditions when A is much larger than E, the percentage error in E may be large but not as large as the error in β. However, in this case the absolute error in E will be small since E itself is small. If the ratio of heat-budget evapotranspiration to lysimeter evapotranspiration is constant over a wide range of atmospheric stability, the possible errors discussed in this paragraph are of little practical importance.

The divergence terms of (1) are minimized by making the temperature and vapor pressure gradient measurements very close to the crop surface. The terms $\overline{(\partial T/\partial z)}$ and $\overline{(\partial e/\partial z)}$ in (3) actually refer to space averages for the entire crop under measurement. Since no convenient space-integrating thermometers or hygrometers exist, a time-average gradient is usually assumed to represent a space-average gradient. When measurements are made at a point just above a heterogeneous plant cover, there is no *a priori* reason to assume that the time-averaged temperature and moisture gradients at that point represent the space-averaged gradients for a much larger area. The scale of the cover variability extends from a few mm (the size of a leaf) to several meters (the scale of the cover patchiness). Most of the unrepresentativeness is removed by swinging the

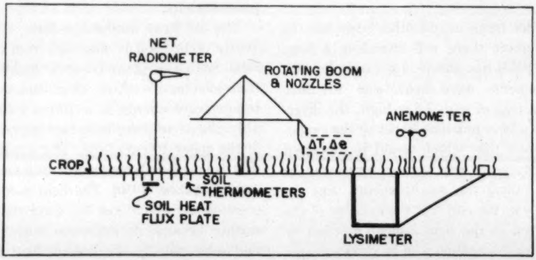

FIG. 2 – Schematic diagram of equipment used to obtain heat budget measurements

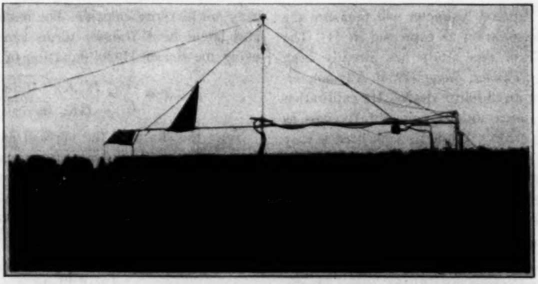

FIG. 3 – Space integrating boom

instruments in a 15-meter arc with the boom shown in Figure 3. Both space and time means are measured with this system. The boom travels the arc in about one minute. During this time an accurate time average is measured. An accurate time average is assured by obeying *Shannon's* [1949] sampling theorem which states that a variable whose highest frequency is *f* is completely specified if the sampling frequency is 2*f*.

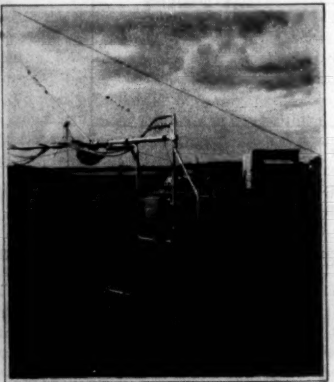

FIG. 4 – Air intake nozzles for measuring temperature and moisture gradients (aspirated thermometers are mounted on parallel bars for position reversal necessary to correct systematic errors)

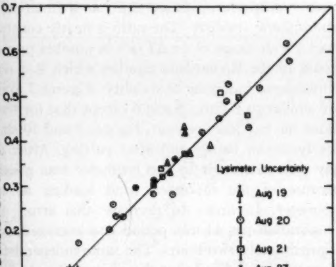

FIG. 5 – Evaporation per 44 minutes from heat budget and lysimeter measurements for August 19, 20, 21, 27, and September 3, 1955

Details of the thermometers and lithium chloride Dewcel hygrometers which meet these requirements have been published [*Tanner* and *Suomi*, 1956]. The temperature and dew point nozzles at the end of the boom are shown in Figure 4. To the authors' knowledge, this is the first time moisture and temperature gradients over a heterogeneous surface have been obtained in this manner. The temperature and moisture differences were obtained over a 60-cm height difference. The lowest position averaged only 10 cm above the mean crop height. On occasion plants even brushed against the bottom sensors, yet with

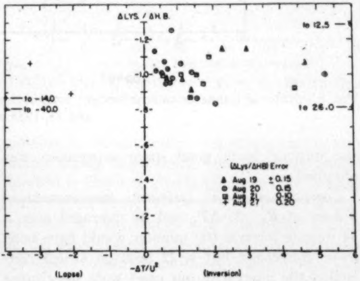

FIG. 6 – Ratio of lysimeter to heat budget evaporation as a function of atmospheric stability for August 19, 20, 21, 27, and September 3, 1955

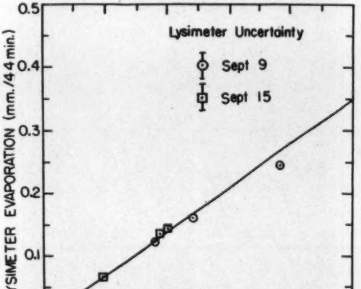

FIG. 7 – Evaporation per 44 minutes from heat budget and lysimeter measurements for September 9 and 15, 1955 after hay was cut

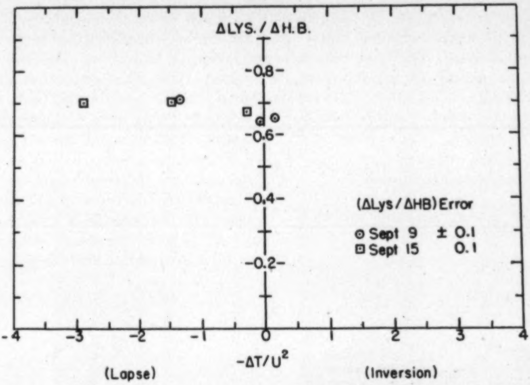

FIG. 8 – Ratio of lysimeter to heat budget evaporation as a function of atmospheric stability for September 9 and 15, 1955 after hay was cut

the moving boom good space integration was obtained.

Comparison with lysimeter measurements—Values of R_n, S, ΔT, and Δe averaged over a 44 minute interval (60 minutes would have been more convenient but a 22 position switch controlled the interval in our case) were substituted into (2) and (4) to yield the heat-budget evapotranspiration estimate. Figure 5 is a comparison of 44-min values of evapotranspiration from an alfalfa field at the University Experimental Farm at Hancock, Wisconsin, calculated from heat-budget measurements and obtained from lysimeter measurements for August 19, 20, 21, 27, and September 3, 1955. The bar in Figure 5 (lower right) indicates the range of uncertainty in the lysimeter measurement (wind loading on the lysimeter). Figure 6 shows the lysimeter to heat budget evapotranspiration ratio as a function of atmospheric stability. The ratio is nearly constant over a wide range of $(-\Delta T/u^2)$, a number proportional to the Richardson number which is a non-dimensional indicator of stability. Figures 7 and 8 are similar to Figures 5 and 6 except that for these dates the hay has been cut. Figures 9 and 10 show the lysimeter before and after cutting. After the hay was cut, error in the lysimeter was greater because of the increased wind loading of the lysimeter. In order to decrease this error, the evaporation per 44-min period was averaged over approximately two hours. The same independence of stability remained, but the ratio of the absolute values of the lysimeter to the heat budget changed materially. This indicates the sampling error of the lysimeter and shows further that it is not an absolute device.

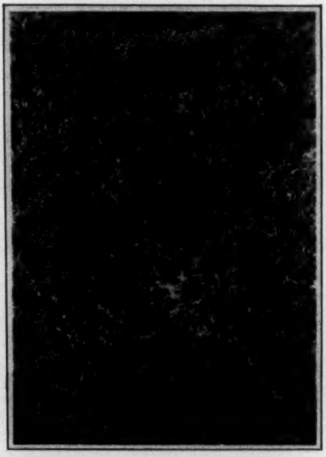

FIG. 9 – View of lysimeter with full cover; dotted line shows the position of lysimeter rim

Comparison with aerodynamic method—Some auxiliary wind data at one meter above the ground was also collected. The actual height above the crop is a function of crop height. It is possible to obtain an additional estimate of evapotranspiration from a product of the wind and the vapor pressure gradient in a manner similar to that used by *Pasquill* [1950],

$$E \propto u \, \Delta e \tag{6}$$

Figures 11 and 12 show a comparison between the heat budget evapotranspiration and $K u \, \Delta e$ where the normalizing constant K was computed to equate the daily evapotranspiration amounts obtained by each method. These figures show that there is little change in the constant over the three-day period and about ten per cent change over a week period due, presumably, to the change in crop height. After cutting, the normalizing constant changed again because of a change in crop height.

FIG. 10 – View of the lysimeter after the hay was cut

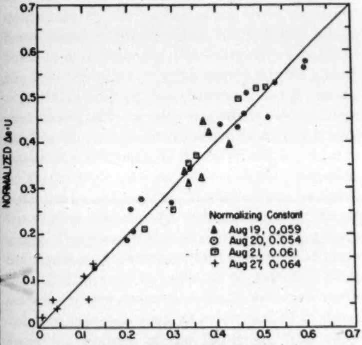

FIG. 11 – Plot of normalized $u \, \Delta e$ vs the heat budget before the hay was cut

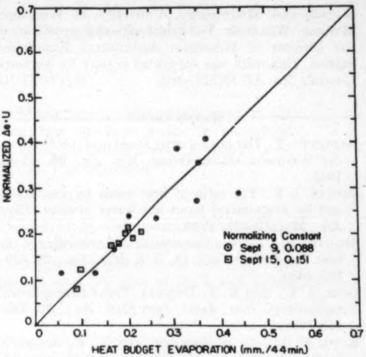

FIG. 12 – Plot of normalized $u \, \Delta e$ vs the heat budget after the hay was cut

This additional wind measurement makes it possible to obtain better evapotranspiration estimates during those times when the heat budget method is likely to give large errors due to small values of either R_n, or $(1 + \beta)$. Evidently a combination of heat budget and a simplified version of the aerodynamic method, enables one to make excellent evapotranspiration estimates over a wide range of atmospheric conditions.

Conclusions—The heat budget has been shown to yield very reliable estimates of evaporation from a field crop on an hourly basis over a wide range of wind speeds and atmospheric stability. By taking the trouble to arrange the experiment to obey Shannons sampling law and to use space integration, measurements can be made close to the crop surface without introducing any error due to the inhomogeneity of the crop surface. When this is done the divergence and storage terms can be neglected and the simple vertical heat budget which results is valid.

While the controversy over any possible difference in K_H, the coefficient of eddy heat transfer, from that of K_w, the coefficient for moisture transfer, is not clearly resolved under the conditions used in this experiment, no difference could be detected. In order to settle this controversy it appears necessary to increase the measurement and sampling accuracy an order of magnitude—no easy task.

Acknowledgment—Grateful appreciation is expressed to K. M. King, Soils Department, Ontario Agricultural College, for his effort during the data collection and reduction. This is a contribution from the Departments of Soils and Meteorology, University of Wisconsin, Madison, Wisconsin. Strength Studies of High-Density Snows

THEODORE R. BUTKOVICH

Abstract—Various strength properties of naturally compacted high-density snows, in the density range from 0.40 to 0.75 g/cm³ are reported. Test results are given for: unconfined compression; unconfined and confined double shear at various lateral pressures; ring, flexural, and centrifugal tensile strength, and torsional strength. The expression

$$\sigma = a(\gamma - \gamma_0)[1 + b(\gamma - \gamma_0)^2]$$

relating the various strengths σ to the density γ of snow fit all the measurements. The constants a and b are different for each strength test, while γ_0, the virtual intercept at zero strength, is constant for all tests. The results of various tests measuring the tensile strength of the snow compare favorably with each other. An attempt to apply some of the known failure rules was unsuccessful.

Introduction—Several experimenters have devoted some time to the study of the shear, tensile, and crushing strength properties of snow. The data they report however, are rather meager, and a comparison of values obtained by the various authors shows quite a difference in their results. It is suspected that this is due to the different types of snow tested, and conditions of temperature or techniques of measurement. Values found in existing publications are primarily for low-density snows, including new snow, old snow, and depth hoar (Schwimmschnee). The work reported in this paper is for naturally compacted snows of higher densities, from 0.40 to 0.75 g/cm³. The term 'high-density snows' as used in this paper means snow of the type that lies below the surface in the upper layers of the northern Greenland Ice Cap, in a no-melt zone. This snow has been naturally compacted by the weight of the overlying snow. Snow found in other regions of the Earth where there is no continuous accumulation is usually of the lower densities, varying from 0.1 to 0.4 g/cm³.

A 100-ft deep pit was excavated and a density and stratigraphy profile was made. From these profiles, layers were chosen which would give a wide variation of densities. In the 100-ft depth a total of 53 layers were selected, with a density variation from 0.40 to 0.65 g/cm³. The layers were sampled by drilling horizontally with a three-inch coring auger. The snow in the horizontal cores was quite homogeneous with respect to the density and grain size. The layers were selected so that no visible variations were included. A single three-inch vertical core hole was sunk an additional 55 ft down from the bottom of the 100-ft pit. The cores taken from this hole were also used in the tests to determine strengths for densities up to 0.75 g/cm³. These cores were less homogeneous because of stratigraphic variation or layering of the snow.

In conjunction with the excavation of the 100-ft deep pit, a snow laboratory was made by excavating an area of about 17 × 9 ft to a depth of eight feet. The excavation was roofed over, and snow platforms along its length were covered with wooden panels to provide table space.

The temperature in the pit below the 20-ft level was about −12°F which is the mean annual surface temperature in this region. All of the cores were left in the snow laboratory at least 12 hr before testing, in order to reach laboratory temperature.

The tests reported here were made on three-inch diameter cylindrical cores with few exceptions. Specimens of the lower density snows (below 0.45 g/cm³) were taken with a standard SIPRE snow tube, 2.28 inches in diameter.

Since the data reported in this paper were taken under field conditions, it was difficult to obtain any sort of temperature control. Laboratory temperature varied from day to day and even hour to hour, owing to the changing outside air temperature and to heat output from the test personnel and the lighting system employed.

It is known that temperature affects the crushing strength of ice, and also the shear, torsional, and tensile strength to a somewhat lesser extent. It was necessary to correct all the values to a common temperature for which 14°F (−10°C) was chosen. The correction used was 1.4 pct/°F for crushing strength, and 0.5 pct/°F for tension and torsional strength values. The correction factor used for tensile strength was used for the double shear tests also, assuming a similar temperature relationship.

These temperature correction factors were taken from temperature effect curves for snow-ice in SIPRE Research Paper 11 [*Butkovich*, 1954]. They are not necessarily accurate for snow, but were the best values available. In any case, the maximum correction, about 15 pct, is less than the scatter obtained for any set of tests before correction and certainly improve the values shown on the graphs.

Crushing strength—Three-inch diameter cylindrical cores were trimmed to lengths of 6.7 ± 0.4 inch (17.0 ± 1.0 cm) in a miter box and the ends finished as nearly plane parallel as possible. A Carver hydraulic press with either a 2000-lb or a 5000-lb Baldwin load cell mounted in its head was used to apply and measure the load. The load cells are rated by its manufacturer to be accurate to ±1 pct of the applied load. The loads were read on a Baldwin strain indicator, on which they were tracked to a maximum value. In many cases the load fell off to a lower value before actual rupture took place.

The snow specimens were broken at the ambient temperature of the laboratory. The rate of application of load was approximately constant, controlled manually and timed with a stop watch. The average rate was 7.4 lb/in^2 sec (0.5 kg/cm^2 sec) calculated by dividing the maximum load by the time required to attain it.

The specimens of snow often broke into characteristic shapes (Fig. 1). After the maximum load was reached and before the actual rupture took place, the specimens visibly deformed. The top and bottom mushroomed, and after rupture the broken specimens had two cones, one at each end, or two partially conical pieces.

The graph of the relationship of crushing strength to density (Fig. 2) shows that the crushing strength of high density snow is a linear function of density. Each point represents the mean value for at least six tests, and each circled point is a mean of a group of similar densities, taken from the same data. A few tests were performed on vertical cores from below the 100-ft level. These values are represented by x's on the graph and are for single tests.

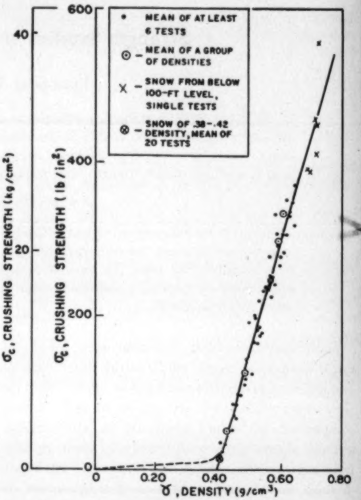

FIG. 2 – Relationship of crushing strength to density, snow from deep pit

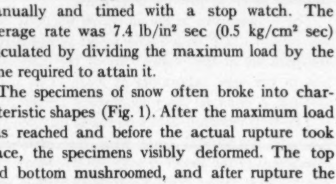

FIG. 1 – Typical compression breaks, snow from deep pit

An empirical relationship obtained from the data shown in Figure 2 for snow of density greater than 0.39 g/cm^3 is

$$\sigma_c = 1418(\gamma - 0.39) \tag{1}$$

where σ_c is the crushing strength in lb/in^2, and γ is the density in g/cm^3. This equation was determined by the method of least squares, has a virtual intercept at 0.39 g/cm^3 density, and holds to a maximum snow density of 0.75 g/cm^3. The broken line is the manner in which it is assumed that the strength values go to zero.

It was impossible to use the three-inch coring auger when the snow was of low cohesion (less than 0.40 g/cm^3 density), so the standard SIPRE snow tube was used. Tests were conducted successfully on snows between 0.38 and 0.42 g/cm^3 density. The values obtained, corrected to 14°F had a maximum temperature correction of 15 pct or 3 lb/in^2. The mean value of 20 tests is shown in Figure 2. For these low-cohesion snows, extreme care was exercised to prevent the samples from

TABLE 1 – *Compressive strength values for 4-cm cubes of snow; temperature 14°F [from Bird and Waterhouse, 1953]*

Mean density	Average unconfined compressive strength	
	Loaded normal to compaction plane	Loaded parallel to compaction plane
g/cm³	lb/in²	lb/in²
0.59	263	207
0.61	391	356
0.68	604	569

falling apart. Snow of lesser density fell apart as it was removed from the snow tube for testing.

A few tests on unconfined compressive strength of snow are reported in SIPRE Report 8 [*Bird* and *Waterhouse*, 1953], giving values obtained for 4-cm cubes. This snow of uniform grain size was disaggregated and artificially compacted. The values (Table 1) are considerly higher than those obtained for Greenland snow. The most likely explanation of this is the influence of the size of the specimens. SIPRE Research Paper 15 [*Butkovich*, 1955] shows the influence of sample size on strength of lake ice. Smaller cross sections give higher strengths, and the ratio of length to width also matters. End constraint increases with decreasing ratio of length to width, preventing the sample from failing under lower stresses.

Tensile strength—Various techniques are available for measuring the tensile strength of snow. One method developed for low density snows (below 0.45 g/cm³) uses a centrifugal tensile strength apparatus. This device consists of a cylindrical container into which snow from a standard SIPRE snow tube can be inserted. The snow specimen is notched slightly at the axis of rotation and driven by an electric motor controlled by a rheostat. RPM at rupture is read on a tachometer. The theory and a nomograph for this apparatus are given in *SIPRE* [1951a]. It was possible to test snows to a depth of 8.7 ft (265 cm) where the density reached 0.44 g/cm³. Testing snows of higher densities and consequently greater strengths would require a greater rpm than was available. The results of these tests are plotted in Figure 2. Each point represents a mean of eight tests. A number of tests using a centrifugal apparatus are reported by *Bucher* [1948]. Values for 23 specimens of density from 0.372 to 0.427 g/cm³ fall in the same range as those shown here with deviations of the same order. The mean density for these tests was 0.411 g/cm³, with a mean tensile strength of 9.2 lb/in². *SIPRE* [1951b] shows some similar tensile strengths obtained at the University of Minnesota, again for the lower density snows.

Another method for determining tensile strength was employed. A ring of the material is caused to fail by applying a compressive load normal to its axis. The test specimens were cut from three-inch diameter cores, to lengths of approximately 2½ in. A one-inch diameter hole was drilled coaxially. Tensile strength was calculated from the equation

$$\sigma_T = \sigma_\theta, = PK/\pi r_0 \qquad (2)$$

where σ_T is the tensile strength at failure, which is equal to σ_θ, the tangential stress at failure. P is the measured load at failure per unit of ring length, r_0 the outer radius of the ring, and K is the concentration factor, which, for these calculations, is dependent only on the ratio $\bar{r} = r_i/r_0$ where r_i is the inner radius of the ring. $K = -10.917$ was obtained from a table in *Ripperger* and *Davids* [1947]. The derivation of the above equation depends on the assumption that the tested material is truly elastic. Within the limitations of this assumption, a ring test will yield the tensile strength of a brittle material. Snow is primarily a viscoplastic material, with insignificant elastic deforma-

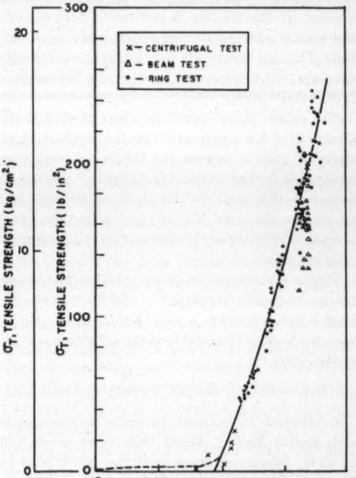

FIG. 3 – Relationship of ring tensile strength to density for high-density snow

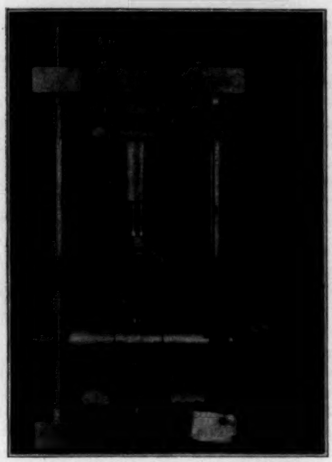

FIG. 4 – Double shear apparatus used for 1955 tests

tion at the lower densities. However, the elastic deformation increases appreciably with increasing density. If the loading is performed fast enough, the plastic effects decrease appreciably in magnitude. The ring specimens were loaded at a high rate (average of 9.5 lb/in² sec) at which the deformation is essentially elastic.

The failure plane for all cases was parallel to the direction of the application of the load. A finite stress at $r = r_i$ causes the failure. Actual tests have shown that, almost invariably, the failure begins at this point in the plane of the load and progresses along the line of the load to the outer boundary. The theory is discussed in the previously cited reference.

Figure 3 is the graph of the relationship of ring tensile strength (corrected to 14°F) to density. Each point represents a single value. An empirical equation was determined from the solid line portion of the curve

$$\sigma_T = 503(\gamma - 0.37)[1 + 2.88(\gamma - 0.37)^2] \qquad (3)$$

A number of flexural strength measurements with center loading beam tests were conducted by S. R. Stearns on snow from the 100-ft level in the deep pit. Values of 31 tests are plotted on Figure 3. The mean corrected to 14°F is 162 lb/in² at a mean density of 0.673 g/cm³. It is slightly lower than that obtained in ring tests.

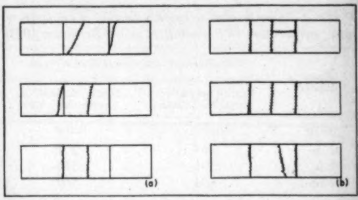

FIG. 5 – Sketch of typical breaks in double shear (solid lines denote apparatus, wavy lines denot breaks), (a) single shear with tension break as generally occurred for densities < 0.50 g/cm³, (b) double shear with tension break as generally occurred for densities < 0.50 g/cm³

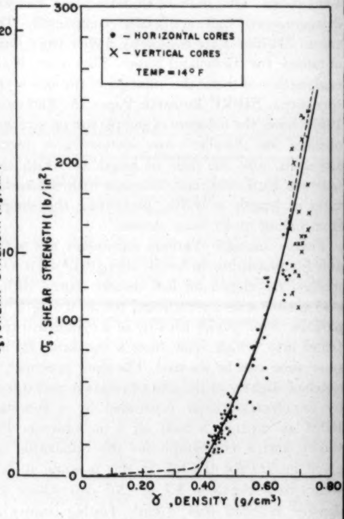

FIG. 6. – Relationship of double shear to density fo high-density snow

Shear strength—The apparatus used was modified Soil-Test, Inc., two-speed mechanica loading press. The shear box was 12-inches lon divided into three equal segments. The cente segment was attached to a mechanical loadin jack, through either a 500- or a 2000-lb provin ring. The two outer segments were attached rigidl to the base of the apparatus (Fig. 4). The tube wa equipped so that confined double shear tests coul also be made. A tapered pin retained a plug at one end of the tube, while a 200-kg Dillon dynamometer attached to a manually loaded piston was used to apply and measure a lateral load. With this device it was possible to obtain a maximum of 60 lb/in² lateral pressure on the three-inch diameter snow sample.

Several series of tests were made to obtain a relationship between density and shear strength for both the unconfined case and confined double shear at various lateral pressures. The specimens were taken horizontally from layers in the deep pit selected to give a wide range of densities. A number of vertical cores taken from below the 100-ft level were included. Loading was at a rate of approximately 5 lb/in² sec. At a very low load, the sample could be heard to fail, although the load did not drop off considerably. If the test was stopped at this point and the sample removed from the shear device for examination, it was always noted that the failure was somewhere near the center of the specimen. This failure was undoubtedly a tension failure similar to that which occurs in bending beams of brittle materials. Loading was continued after the tension failure, and the load increased until a new failure occurred where the load dropped off to zero.

Two types of failures were noted: (1) when the snow density was less than 0.50 g/cm³, the sample generally failed on only one shear plane (Fig. 5a); (2) when the density was greater than 0.50 g/cm³, the samples failed on both shear planes (Fig. 5b). However, all the data reported here were treated as though a double shear failure occurred in all cases. Figure 6 shows the relationship of the unconfined shear strength to density. The points represent values for single tests of horizontal cores, while the x's represent single values obtained from vertical cores. The relatively high amount of scatter is attributed to stratification of the snow, although higher strengths would be expected for the same mean density of horizontal (more homogeneous) cores. The upper broken line is a correction in this sense.

Table 2 – *Shear strength of disaggregated, artificially compacted snow from Fuchs* [*1949*]

Density	Shear strength	
g/cm³	kg/cm²	lb/in²
0.487	1.5	21.3
0.615	2.7	38.3
0.631	4.9	69.6
0.686	8.1	115.0
0.862 (snow ice)	12.2	173.2

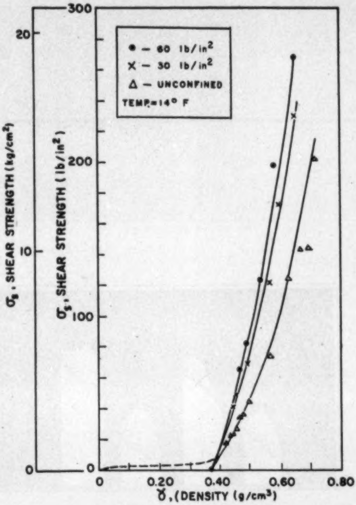

Fig. 7 – Relationship of shear strength to density for 0, 30, and 60 lb/in² lateral pressure

Several investigators have reported values for unconfined shear strength of snow. *SIPRE* [1951a] gives some values for lower density snows, and zero normal load. The mean is 7.1 lb/in² (0.5 kg/cm²) for 0.420 g/cm³ density. ***Fuchs*** [1949] reports a single shear value for disaggregated, artificially compacted snow as a function of temperature. Table 2 gives values taken from his curves at −10°C (14°F). These values are somewhat lower than those found for the Greenland snow, but there are several factors which may explain the difference. The shear specimens were all loaded at a much faster rate, in 1 to 2 sec. to failure. Another and probably more important factor was that the specimens were tested only seconds after they were compacted, not allowing age hardening.

Another series of tests was made using lateral pressures of 5, 15, 30, 45, and 60 lb/in². The sample length was 10.5 inches. The remaining portion of the 12-inch tube was occupied by the plug at one end to retain the test specimen, and the piston device with the Dillon dynamometer at the other. The desired lateral pressure was first ap-

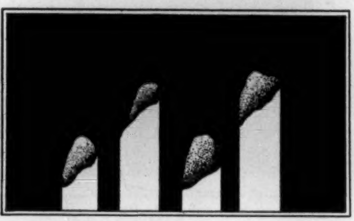

FIG. 9 – Typical torsion breaks, high-density snow from deep pit

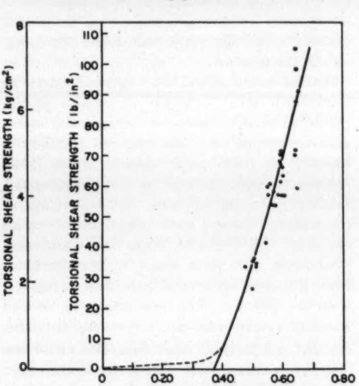

FIG. 10 – Relationship of shear strength to density for high-density snow

plied, and immediately afterwards the shearing force, keeping the lateral pressure constant.

After shear stress was applied, it was noted, for the specimens subjected to the low lateral pressure of 5 and 15 lb/in², that it was necessary to move the piston out to maintain a constant load, indicating that the snow specimen was expanding. For the higher lateral pressures of 45 and 60 lb/in², it was necessary to move the piston in to maintain a constant load, indicating a decrease in volume of the specimen. This was not due to simple consolidation of the snow because in several cases no decrease in volume occurred under 60 lb/in² lateral pressure during a relatively long period of time before application of the shear stress.

Figure 7 gives the relationship of temperature corrected shear strength to density curves for 0, 30, and 60 lb/in² lateral pressures. An empirical equation was obtained relating the shear strength to density for the three curves which is

$$\sigma_s = a(\gamma - 0.37)[1 + b(\gamma - 0.37)^2] \quad (4)$$

where σ_s is the shear strength in lb/in², and a and b the constants for the various lateral pressures. The values for a and b at 14°F are 333 and 7.04 respectively for zero lateral pressure; 558 and 5.44 for 30 lb/in² lateral pressure, and 643 and 6.13 for 60 lb/in² lateral pressure.

Torsional strength—A method for measuring shear stress by applying a torque to three inch diameter cores was tried on a few specimens. Only higher density snow was used because the handling necessarily would be damaging to the snows of lower density. Horizontal cores were taken for these tests from 0.50, 0.55, 0.60, and 0.65 g/cm³ density layers in the deep pit.

The apparatus (Fig. 8) consisted of a device which holds one end of the specimen stationary while the other end is free to rotate. A spring balance is attached to a lever arm on the rotating end for the determination of the torque. The apparatus was designed for square-end cross sections. It was necessary to put ends of the core into metal boxes, pack slush around them, and wait until it froze.

The rate of loading was approximately constant at 9 lb/in² sec. This relatively fast rate was used to reduce the plastic effects described in the tensile strength section of this paper.

The types of breaks were typical 45° helical torsion breaks that usually occur with brittle materials (Fig. 9). The stress distribution here is such that failure is in tension rather than in pure shear.

The torsional strength was calculated from an equation whose derivation can be found in *Timoshenko* and *MacCullogh* [1949, chap. 9]. The equation is

$$S = 16M_t/\pi d^3 \qquad (5)$$

where S is the unit shearing stress up to the elastic limit, M_t is the applied torque, and d is the diameter of the circular cross section. This equation is said to hold only within the elastic limit. In case of failure, the value obtained is called the torsional modulus of rupture.

Figure 10 is a plot of the relationship of the torsional modulus of rupture to density. The values are somewhat lower than those obtained in unconfined double shear or ring tension. High-density snow, which is a brittle material relatively weak in tension, when twisted, fails in tension on a plane inclined approximately 45° to the planes on which the shear stress occur.

Discussion of results—For all the strength data reported here, the density for which the extrapolated strength goes to zero lies between $\gamma_0 =$ 0.37 to 0.40 g/cm³. An attempt was made to express all the strength data in a common equation, involving only a difference in constants. It was found that the expression

$$\sigma = a\Delta\gamma(1 + b\Delta\gamma^2) \qquad (6)$$

could be made to fit all the curves, where $\Delta\gamma = \gamma - \gamma_0$ and γ_0 is the density at $\sigma = 0$. For the relationship of unconfined compression to density, being linear, the intercept was $\gamma_0 = 0.39$ g/cm³. For the relationship of ring tensile strength, torsional strength, and double shear to density for 0, 30, and 60 lb/in² lateral pressures, γ_0 was chosen as 0.37 g/cm³. A straight line was drawn through the intercept tangent to the curves; a in (6) is the slope of the stright line. The value of b which is an indication of the curvature, was determined by selecting a point on the curve at 0.67 of the maximum strength value and substituting the value of σ and $\Delta\gamma$ from here. The values of a and b that best represent the empirical data are shown in Table 3. The use of a virtual intercept is not meant to indicate that snow of lower densities have absolutely no strength, since strengths have been measured for these snows. *Kuroda* [1929] measured 63 g/cm² (0.9 lb/in²) shear strength for loose powder snows. A different type of structure exists below this critical density at the intercept. It has been observed that snow disaggregated and heaped always assumes an uncompacted density between 0.35 and 0.42 g/cm³. This is a characteristic of the substance snow and not of where snow came from. It is known that strength is some function of the contact area of the grains. At the lower densities, the number of contacts and the total contact area between grains decrease very rapidly. Studies are presently being conducted at the SIPRE Laboratory to determine this relationship.

TABLE 3 – *Values of constants*

Type of test	a	b
Unconfined compression	1418	0
Tension	503	2.88
Double shear, unconfined	333	7.04
Double shear, 30 lb/in² lateral pressure	558	5.44
Double shear, 60 lb/in² lateral pressure	643	6.13
Torsion	230	5.73

The evaluation of the ring test for the determination of the tensile strength of snow shows this test to yield results slightly greater than, but comparable with, those obtained by other means. The flexural strengths of simple beams obtained by Stearns agree very well with ring tension values, although the beam tests show slightly more scatter. The strength values obtained with the centrifugal tensile strength apparatus also fall in line (Fig. 2) although done on the lower density snow.

It can be expected that higher values of tensile strength would be obtained with ring tests than

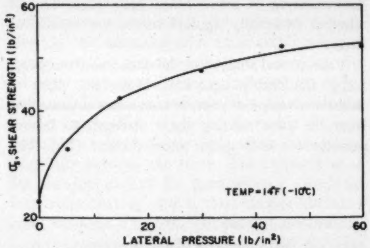

FIG. 11 – Relationship of shear strength to lateral pressure for snows of mean density of 0.45 g/cm³; each point represents a mean of ten tests

with beam or direct tension tests because of the extremely small volumes with critical stress involved in the rings. Among others, *Jellinek* [1957] shows that an increase in tensile strength occurs as the volume of the test specimens decreases. His analysis is based on a definable distribution of imperfections in ice. This distribution is considered in relation to the strengths of the imperfections. Each imperfection can withstand stresses up to a certain critical value. When the critical stress is exceeded, the imperfection opens up to a crack and the specimen ruptures. Since the probability for the weakest imperfections to occur in small volumes is less than for larger volumes, smaller volumes will give higher values of strength. The maximum tensile stress in the critical section occurs at the inner boundary $r = r_i$. A slight plastic deformation occurs directly under the load which causes such a redistribution of load that the stress is distributed over a finite area. If the material is strong in compression, such a redistribution would not materially affect the stress at an appreciable distance from the load.

The tests for the determination of the shear strength of snow were performed in direct shear. The results by themselves are quite reproducible. The unconfined shear tests give results of approximately the same magnitude as the ring tension values, with the latter being somewhat higher, probably because of the volume effect discussed in the previous paragraph. High-density snow is a granular substance, with more or less rounded particles. The total contact area of the bonds between the particles is related to the density. Both shear and tension failures are primarily intergranular rather than intragranular, with bonds being broken rather than the grains. For an open network such as exists for snow, it is quite obvious that shearing of bonds takes place regardless of whether externally applied forces are tensile or shear.

A theoretical analysis of the data was attempted, using Coulomb's equation. However, when a Mohr's envelope of rupture curve was constructed from the data relating shear strength to lateral pressure for 0.45 g/cm^3 snow density (Fig. 11), the envelope of rupture has a pronounced curvature instead of being a straight line. Two other known theories of failure, that is Tresca's maximum shear stress rule and Nadai's octahedral shear stress rule were considered for the analysis, but were rejected because they were not found to be useful.

Studies on Wave Propagation in Granular Media

PAUL LIEBER AND ARTHUR FARMER

Abstract—Experimental studies relating to the propagation and attenuation of disturbances in unconsolidated materials encouraged a theoretical investigation suggesting a mechanism governing propagation in such materials. From these physical considerations it is inferred that a disturbance imparted to a granular material is propagated in two principal parts. One consists of a wave of small amplitude which anticipates a wave of much higher amplitude propagating at a lower velocity. The first wave is called here a precursor and is identified with the visco-elastic deformation of the grains of the unconsolidated material. The second component propagating at a lower velocity and carrying most of the energy imparted by the disturbance is identified with consolidation, accomplished by filling the voids between the grains. It is thus inferred that there would be appreciable dissipation of energy associated with the second wave and little attenuation of the precursor wave. Further experiments were conducted to check these conclusions. The results of these experiments show the composite wave structure predicted from theoretical considerations.

Introduction—In attempting to extend mathematical studies on wave attenuation in visco-elastic materials, *Mattice* and *Lieber* [1953], to the depiction of the propagation of large disturbances through granular media the need for understanding the mechanism of propagation in such materials became evident. Some basic theoretical and experimental work has been carried out relating to the propagation of elastic waves in granular media by *Takahaski* and *Sato* [1949], *Gassmann* [1951], *Mindlin* and others [1951], and *Duffy* and *Mindlin* [1956]. In these studies the granular materials are represented by models consisting of rigid and consolidated elastic spheres. These investigations model a terminal phase of a more general transmission process and mechanism which is considered in this paper. It was therefore helpful to devise new experiments more representative of actual conditions to guide our thinking on this problem.

From physical considerations it appeared that the attenuation of a pulse in granular material is accounted for in large measure by the dissipation accompanying consolidation. From this it was inferred that the packing caused by the pulse decreases in the same direction the wave attenuates. Also possible, is the visco-elastic transmission of a pulse when repeated pulses of equal magnitude no longer increase the packing of the sand. Accordingly, if the pulse is increased in magnitude; the sand may continue to consolidate until it becomes virtually consolidated with respect to this magnitude. At such a time the pulse will again be transmitted visco-elastically.

Preliminary experiments were designed to check this reasoning and provide a basis for gaining physical insight to the mechanism governing propagation. The results of these experiments served as a guide in formulating a physical theory for a mechanism governing the propagation of a finite disturbance in granular materials. In these experiments the energy dissipated by dynamic consolidation and by intergranular friction was accurately measured.

The physical theory leading to this mechanism is based upon Hertz's generalization of Gauss' principle of least constraint. In this extension of Gauss' principle it is shown that it remains valid for impulsive loading and when the conditions of constraint depend explicitly upon time. The theory treats a granular material such as sand as a system of discrete particles which retain their identity in all encounters and are capable of moving relative to each other. The cases of perfectly smooth and rough particles are discussed separately. In addition to explaining qualitatively the results of the preliminary experiments, the physical theory predicts the existence of a small-amplitude precursor wave anticipating the wave carrying the principal part of the energy imparted by a disturbance. The precursor wave is identified with the elastic deformation of the grains and it is propagated with the velocity of a wave transmitted elastically between the grains. The propagation of the principal part of the disturbance is associated with consolidation and is thus propagated at a lower velocity. The principal part of the disturbance is therefore strongly attenuated by the large friction forces accompanying consolidation.

Experiments were then designed and conducted to detect the composite wave structure and in particular the precursor wave predicted by the propagation mechanism.

PRELIMINARY EXPERIMENTS

Consolidation produced by transient loads—A transparent plastic tube one and one-half inches in diameter and eighteen inches long was fitted with a brass cap at one end (Fig. 1). A steel piston was machined to fit the inside diameter of the tube.

The one end was capped and the tube filled with sand. To facilitate observation colored sand layers were introduced at intervals of one and one-half inches between uncolored layers. The initial locations of the colored layers were marked in the tube.

The piston was placed in the open end of the tube in contact with the sand and then struck repeatedly by a hammer and the new locations of the colored layers observed.

Visual evidence of progressive consolidation—It was found that after the first impact the packing near the piston, or source, was appreciably increased. This increase of packing diminished rapidly away from the source until only the original packing was evident. Following the second impact the packing near the source increased further, but only slightly, and the zone of maximum packing moved away from the source. Beyond that region the packing attenuated as before. Subsequent impacts had the same effect as the second impact, extending the packing into the sand.

When, following several impacts, the packing extended into three-fourths of the tube, the layers of sand in the remainder of the tube moved toward the piston. This may be explained by the packing near the piston becoming so large that the friction force between the sand and the tube resulting from a blow caused the plastic tube to move before the last one-fourth of the sand. Thus the relative movement of the colored layers would be toward the piston. However, this effect is a characteristic of the tube and is extraneous to the purpose of the experiment.

Energy dissipation in sand—The same plastic tube was supported as a pendulum, using a V-arrangement of two wires at each end to prevent lateral motion. A ten pound steel weight was also suspended by a similar V-support so that at the bottom of its arc it would strike the piston. Potential energy was introduced by deflecting the hammer along its arc to a pre-assigned height and arresting it there with an electromagnet.

A sheet of aluminum was placed parallel to the plane of the arcs subtended by the two pendulums.

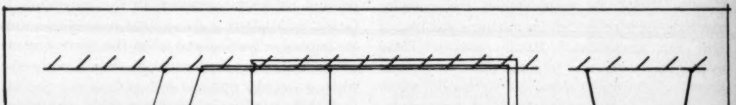

FIG. 1 – Apparatus used to measure energy dissipation in sand

It was covered with tracing paper on the side facing the pendulums. Pointers were attached to the tube and weight, extending approximately $\frac{3}{16}$ inch from the aluminum sheet. A magneto connected to the pointer and the sheet caused sparks to burn holes in the tracing paper. This provided an accurate trace of the motion of both pendulums, without impairing their motion.

The hammer was released by the electromagnet and the spark-producing magneto started. The pendulum then struck the piston. As the collision does not lead to a complete transfer of energy, the hammer would follow through. The tube of sand was allowed to attain its maximum height and was then arrested upon its return to prevent a further collision.

Impacts corresponding to the same initial height of the hammer were repeatedly applied. Following each impact, the tracing paper was moved and a reference line scribed using a level.

By subtracting the energy remaining in the hammer after collision from its initial energy, the energy transferred to the piston in the sand tube was determined. Using the weight of the sand tube and its initial and maximum elevation, the mechanical energy remaining in the tube and its contents were determined. The difference between the initial and terminal values of the mechanical energy in the tube is the energy absorbed by the sand.

In order to observe the reversible deformation of the sand as distinguished from the irreversible deformation (dissipative) the initial and terminal position of the piston relative to the tube were recorded. Using the apparatus just described, a pencil was attached to the plastic tube and a piece of paper taped to the shank of the piston. The pencil trace on the paper measured the motion of the piston, relative to the tube, produced by striking the piston with the hammer. This measurement was determined by the reversible and irreversible deformations. Following the impact, there is a partial recovery of the piston toward its initial position. This recovery is associated with the elastic deformation. The difference between the initial and terminal positions of the piston is therefore a measure of inelastic deformation.

Measurement of energy dissipation—It was found that when sand was poured in the tube without further packing it absorbed approximately 60 pct of the energy imparted by the first impact and dropped off sharply on the next two impacts (Fig. 2) thereafter remaining constant at about 43 pct for impacts of equal intensity. If the energy imparted was doubled, the energy absorbed increased to approximately 50 pct and then decreased as before to approximately 43 pct for the second impact and subsequent impacts of equal intensity.

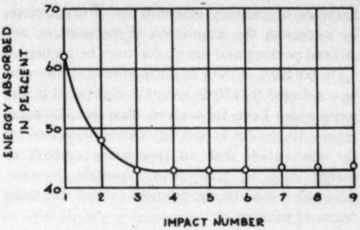

FIG. 2 – Per cent of impact energy absorbed on successive blows by sand confined in a tube

When the dissipation attained the asymptotic value of 43 pct subsequent packing was not visible. The energy imparted by the hammer was larger than the energy transferred in the visual experiment on the progression of packing. Thus, following two or three impacts, the sand became so packed that the tube was accelerated by friction between the sand and the tube wall. It is probable that the energy dissipation occurring for subsequent blows was caused by friction against the wall of the tube accompanying the seemingly elastic deformation of the sand, by internal friction, and by motion of the sand near the capped end of the tube. The latter was verified by removing the cap leaving a free sand surface. It was found that the sand did not lurch forward as if suddenly energized by a wave passed through it. This suggests that most of the energy is transferred to the tube by friction rather than by a normal force on the cap.

Comparison of reversible and irreversible deformations—The initial impulse caused a permanent movement of the piston that was approximately four times the reversible deformation. The second impulse produced a permanent deformation that was approximately twice the reversible deformation. The permanent deformation produced following the third impulse was somewhat smaller than the reversible deformation. All the subsequent impacts produced reversible deformations. The permanent displacement can therefore be attributed primarily to consolidation.

This experiment considered in conjunction with the previous one shows that the energy dissipated decreases significantly with increased consolidation of the sand. Thus, considerable dissipation is found to accompany consolidation. Furthermore, by increasing the magnitude of the impulse, additional packing and dissipation may be produced.

On the basis of the visual experiment it may also be concluded that little energy is dissipated in the zones which have for a given blow become saturated with respect to packing. This is supported by the observation that an appreciable amount of energy must be transmitted through the consolidated region to significantly extend the same degree of packing.

A mechanism governing the propagation of a disturbance in granular media—The correlations found in the experiments described between propagation and consolidation were helpful in suggesting a mechanism that may govern the propagation of a disturbance in granular materials. According to this mechanism, a disturbance propagates in such materials in two principal parts. The first part consists of a weak precursor wave associated with essentially elastic deformations of the grains transferring momentum normal to their contact surfaces, and thus propagating at the speed of sound in the grains. The second part, propagating at a lower velocity transmits most of the energy imparted by the disturbance, is identified with the interpenetration of the grains, and thus with consolidation.

The existence of a precursor wave and its relatively small amplitude was inferred by assuming that Gauss' principle of least constraint can be extended to collision phenomena. Such an extension to impulses was later found to have been carried out by *Hertz* [1896, pp. 76 and 253]. In adapting Gauss' principle to a collision model depicting grain interaction, it is here postulated that the grains retain their individuality in the course of time (during interaction) and that this is expressible by conditions of constraint which determine the admissible displacements of the individual grains. The conditions of constraint identified with the individuality of the particles may be expressed in geometrical terms by asserting that the grains cannot coincide. Displacements compatible with these conditions of constraint are then the virtual displacements of the system. Only displacements which do not bring the particles into coincidence are therefore admissible.

If the grains are perfectly smooth, then momentum is transferred only in directions perpendicular to the surfaces of contact and the forces generated by the conditions of constraint cited above are perpendicular to these surfaces.

According to Gauss' principle of least constraint the real motion of such a system is determined by the condition that the total constraint generated in this manner during collision be a minimum. This requires that the total change of momentum normal to the contact surfaces be less for the real motion than for any other motion consistent with the constraints and the initial conditions. In the presence of voids, the particles minimize constraints by interpenetration.

The energy transmitted normal to the contact surfaces which according to Gauss' principle is a minimum for the actual motion is propagated elastically between the grains at the speed of sound in the grains, and is identified here with a precursor wave. Strictly speaking, the propagation between the grains is elastic only if they are regarded as perfectly elastic bodies and if friction between the grains is neglected. The energy transported by grain interpenetration is propagated at a lower velocity and according to Gauss' principle should propagate most of the energy imparted by a disturbance. It is also inferred that when the voids are not sufficiently large to admit grain displacement leading to consolidation, all of the energy imparted by a disturbance would propagate elastically and a distinct precursor wave is not to be expected.

Anthropomorphically speaking, the above considerations may be expressed by the statement: The particles move where they encounter minimum resistance and thus naturally penetrate the voids rather than generate large collision forces whenever and wherever such alternatives present themselves.

In order to establish the physical reasoning leading to the mechanism outlined above on an accepted physical foundation, it is necessary that Gauss' principle be valid when the constraints depend explicitly upon time; as is the case when conditions expressing the impenetrability of the grains are formulated in a Galilean frame of reference. Hertz has demonstrated with complete generality that Gauss' principle holds when the equations of condition (constraint) contain time explicitly.

The next problem is to extend the application of Gauss' principle to such cases where the grains are not perfectly smooth. As friction forces resisting consolidation are then generated it is necessary to consider their effect upon the composite wave structure inferred in the case of perfectly smooth grains. The friction force also affects the precursor in a manner which probably can be well represented by a visco-elastic material.

Hertz [1896, pp. 76 and 253] postulated that the particles of a mechanical system are in general rigidly connected by differential equations of condition and that the motion of the system as a whole is governed by a law that is formulated without introducing the concept of force. In this manner Hertz deduced the Newtonian laws of motion and the principles of analytical mechanics and demonstrated that the forces impressed within and upon a system are determined by rigid connections existing between its particles and those of other systems. In demonstrating this Hertz introduced the concept of concealed masses whose connection with the observable particles is made apparent by the forces which they impart by their motion, to the observable particles.

Although by postulating the existence of concealed particles and rigid connections Hertz was able to deduce the Newtonian laws and the principles of mechanics from his fundamental law, he recognized the need to justify these rigid connections on strictly physical grounds. If it is postulated that interacting particles have an individuality which is maintained in the course of time then conditions which exclude displacements that would bring particles into coincidence may be regarded as rigid conditions applying to all particles of a system. According to this idea, the rigidity of the constraints is identified with and determined by the individuality of the particles. This may provide a physical concept upon which the notion of rigid connections, which are indispensable to Hertz's brilliant work, may be founded. If all the strictly rigid connections of a mechanical system are thus attributed to the individuality of its observable and concealed particles then it follows from Hertz's mechanics that all forces generated within the system are determined by this property of matter, that is, by its impenetrability.

In a granular material the observed particles are the individual grains, whereas the particles that account dynamically for the friction forces between the grains are in the sense of Hertz, the concealed particles of the system. Accordingly, the interaction of the concealed masses with each other and with the observable particles (the grains) are assumed here to be subject to the rigid connections through which their individuality is asserted. (Hertz postulated that in general the rigid connections may be expressed by linear homogenous differential equations relating the first differentials of the moduli of the vectors denoting the positions of the particles. Only in the particular case of Holomonoic systems are these equations integrable and are thus equivalent to finite equations of condition.)

It is now convenient to formulate Gauss' principle of least constraint analytically so that it may be referred to in describing a mechanism for propagating a disturbance in granular materials consisting of rough grains.

Consider a mechanical system consisting of particles with masses $m_1, m_2, \cdots m_m$, subjected to the impelling forces $F_1, F_2, \cdots F_m$, respectively. Let these particles be connected by rigid conditions of constraint which determine the admissible displacements that may be produced by these forces. In order to introduce a measure of constraint in terms of which Gauss' principle may be stated, it is sufficient to consider a representative particle of the system. Let $\overline{OA_1}$ be the displacement of particle i that would be produced by the impelling force F_i in time dt if the particle were free. Because of the constraints, the actual displacement in this time interval will be $\overline{OB_i} \neq \overline{OA_i}$. The constraint thus produces a change in the motion represented by the vector difference $\overline{OC_i} = \overline{OA_i} - \overline{OB_i}$. Gauss' principle states that the actual displacement of a system in time dt is determined by the condition that the sum $C = Mi\ \overline{(OC_i)}^2$ be a minimum. Thus the principle asserts that C, which measures the total constraint of the system, shall be less for the actual motion than for any other motion compatible with the constraints.

It is noted that the contribution of particle i to the total constraint of the system is weighted by its mass m_i. Accordingly, the minimization of C implies that the system moves so that changes of displacement produced by the constraints of the smaller masses are increased if by so doing the changes of displacement produced by the constraints of the larger masses are decreased.

Consider a mechanical system consisting of particles identified with both the individual grains of a granular material and with the concealed masses whose motion accounts for the friction forces acting tangent to the grain surfaces, when they move relative to each other. The masses of the grains which in this model are assumed to retain their individuality in the course of time are clearly much larger than the concealed masses accounting for the friction forces resisting consolidation. The finite volume of the grains should in general also be taken into account, in the consideration of the constraints generated as a consequence of the grain individuality. Accordingly the constraints connected with the displacement of the grains, in rotation as well as in translation should be considered, where the former are weighted in the expression for the total constraint by the moments of inertia of the grains.

A mechanism for propagating a pulse in a granular material consisting of rough grains may be described in terms of this composite mechanical system by considering qualitatively the constraints which account for the forces applied normal and tangent to the contact surfaces.

The grains interact by transferring momentum normal and parallel to the contact surfaces. From the above considerations, these forces have their origin in the constraints associated with the grain masses and with the concealed masses respectively. If we now assume that the grains and the concealed masses constitute a composite mechanical system governed by Gauss' principle, it follows that the change in displacement admitted by the forces originating from the constraints associated with the grains are much smaller than those admitted by the concealed masses.

If a disturbance is applied to some grains imbedded in a granular material they are accelerated, and if not initially in contact, move until they engage neighboring grains to which they impart forces normal and tangent to the contact surfaces. The constraining forces generated normal to the contact surfaces may be resolved into forces acting through the centers of mass and couples. The constraints are then respectively proportional to the masses and the moments of inertia of the grains. In the first case the grains assert their individuality by resisting displacement of their centers of mass and in the second case by resisting displacements in rotation.

It follows that changes in displacement admitted by constraints generating the normal stresses should be much smaller than those admitted by the constraints identified with the tangential stresses. As this result appears to be general within the framework of the physical theory in which it is obtained, it may be used qualitatively to infer a mechanism for transmitting a pulse in granular materials. Since the mode of transmission of a pulse in such materials is determined by the motion of its grains compatible with all of the constraints of the system, it follows that in the presence of voids the transmission of energy accompanying displacements tangent to the contact surfaces, would be much larger than the energy transmitted normal to these surfaces. This implies as in the case of perfectly smooth grains that a pulse would be transmitted in essentially two distinct parts. The first part, identified with the normal stresses, would therefore have a small amplitude and propagate with the speed of sound in the grains. The speed of sound is a function of the initial normal contact stress as reported by *Duffy* and *Mindlin* [1956] according to their experimental results. The propagation of the second part is identified with consolidation and would therefore, transmit most of the energy at a velocity which is appreciably lower than the speed of sound and would be strongly attenuated by the friction forces acting tangent to the contact surfaces.

Note that the mode of transmission of a pulse in granular materials proposed here has been inferred without using the conservation laws for momentum and energy. This is possible since the transmission of energy and momentum in the system considered, is completely determined by the preferred paths of the particles which have been here directly inferred from Hertz's extension of Gauss' principle of least constraint. Accordingly, the concept of force and energy are not used in the statement of Hertz's fundamental law but rather appear as consequences of this law.

When voids sufficiently large to accomodate the grains are not available the composite wave structures consisting of a weak precursor propagating acoustically, followed by a strong and rapidly attenuating pulse identified with consolidation, should coalesce into a single pulse propagating at the speed of sound. This pulse may also be attenuated although to a lesser degree by intergranular friction.

Some energy may also propagate elastically through couples resulting from the normal stresses applied to grains of finite size. This may produce another elastic wave propagating at a lower velocity than the precursor. It is believed, however, that this wave would probably be of much smaller amplitude than the precursor and be masked by the large disturbance identified with consolidation. If the mechanism proposed here is essentially valid, elastic waves of the same type as the precursor would be repeatedly generated and radiated as weak secondary waves from the principal part of the pulse identified here with consolidation.

The experiments described in the following section of the report were designed to evaluate the propagation mechanism proposed here. In so doing, the precursor wave predicted by the mechanism was detected in all cases where it was anticipated.

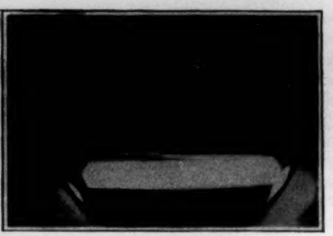

FIG. 3 – A disturbance propagated through two inches of dry sand, as recorded by a strain-gage pickup; 1000 cycles per second sweep; (1) precursor wave; (2) sharp rise of principal disturbance (note that the maximum amplitude of large disturbances is off screen); (3) coda of wave (see Fig. 5); (4) sweep of oscillograph before and after the disturbance

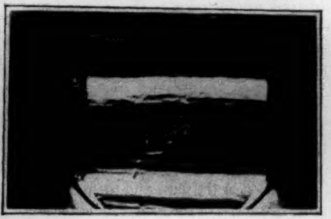

FIG. 4 – A disturbance propagated through five inches of sand, as recorded by a strain-gage pickup; 1000 cycles per second sweep; (1) precursor wave; (2) sharp rise of principal disturbance (the maximum amplitude is off screen); (3) coda of wave (see Fig. 5); (4) sweep of oscillograph before and after the disturbance; (5) displacement of neutral position of the beam; this occurred after the mechanical disturbance

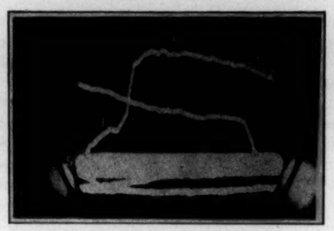

FIG. 5. – A disturbance propagated through 30 inches of sand, as recorded by a strain-gage pickup; 60 cycles per second sweep; (1) precursor wave; (2) sharp rise of principal disturbance; (3) maximum amplitude of principal disturbance; (4) coda of principal disturbance (the recurrent sweep of the oscillograph causes the line terminated at the right to be continued at the left of the screen; thus the image of the latter portion of the wave is superimposed upon the image of the first portion of the wave); (5) sweep of the oscillograph before and after wave

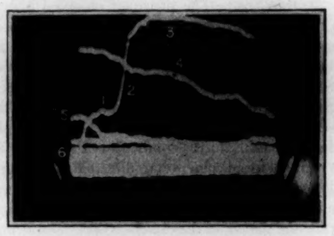

FIG. 6 – A disturbance propagated through 30 inches of sand, as recorded by a strain-gage pickup; 60 cycles per second; (1) precursor wave; (2) sharp rise of principal disturbance; (3) maximum amplitude of principal disturbance; (4), (5) coda of principal disturbance (the recurrent sweep of the oscillograph causes the line terminated at the right to be continued at the left of the screen; thus the image of the latter portion of the wave is superimposed upon the image of the first portion of the wave); (6) sweep of the oscillograph before and after disturbance

EXPERIMENTS RELATING TO THE PRECURSOR WAVE

Instrumentation—A pickup was constructed to record time changes of displacement of a granular material subjected to impulsive loads. The pickup consisted of a strain gage glued to a 0.008-inch thick steel diaphragm resting on a shoulder machined $\frac{3}{8}$ inch from the open end of a $1\frac{1}{2}$-inch long circular cylinder closed at one end. A circular insert was used to retain the diaphragm on the shoulder. The strain gage was in one arm of a wheatstone bridge. The unbalanced voltage produced by deflections of the diaphragm was amplified and fed to a cathode-ray oscilloscope. The screen was photographed with a Dumont cathode-ray oscilloscope record camera. The pickup exhibited the characteristics desired, being only sensitive to deflections of the diaphragm.

The pickup was imbedded in dry sand and so oriented that the diaphragm was normal to the direction of propagation produced by a disturbance at the surface of the sand. The depths of the sand layers used in these experiments were approximately 2, 5, and 30 inches. The packing varied with repeated blows on the piston. The shutter of

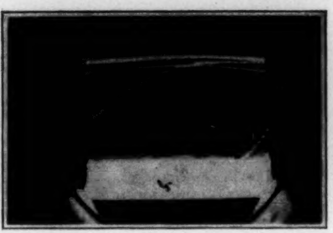

FIG. 7 – A disturbance produced under conditions similar to those in the sand tests, propagated through two inches of modeling clay; 1000 cycles per second sweep; (1) rise of disturbance; (2) rise of disturbance, continued because of oscillograph's recurrent sweep; (3) maximum amplitude of disturbance; (4) coda wave; (5) sweep of oscillograph before and after disturbance; the absence of a precursor is noted

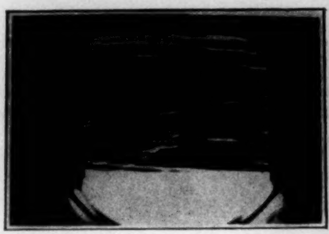

FIG. 8 – A disturbance propagated through two inches of modeling clay, as recorded by a strain gage pickup; gain of oscillograph increased to accentuate region (1) of the previous photograph, 1000 cycles per second sweep; (1) rise of disturbance; the absence of a precursor wave is noted

the Dumont camera was opened before and closed after the impulse.

Measurements—The precursor observed here is a small amplitude, sharp wave that preceded another disturbance having a much larger amplitude. In all photographs the horizontal axis measures time and the vertical axis the displacement of the diaphragm, which is proportional to the force imparted to it by the sand. The photographs thus give a time history of the force transmitted to a plane perpendicular to the direction of propagation of the wave. The heavy horizontal line is produced by numerous sweeps made by oscillograph while the shutter of the camera is open. The strain-gage pickup using an alternating current amplifier with large capacitance is capable of sustaining a steady signal for a sufficient period of time to record the wave shape. A two-inch specimen of loosely packed sand requires a sweep of about 1000 cycles per second to separate the precursor from the principal disturbance. When the sensitivity was increased to accentuate the precursor wave the maximum amplitude of the strong wave was off the oscillograph screen as shown in Figures 3 and 4. With a five-inch sand specimen the time interval separating the arrivals of the two disturbances is increased.

As the depth of sand was increased to 30 inches it was found that the time interval separating the arrival of the two waves increased further. This definitely established that the two disturbances travel at different velocities. The divergence of the waves with increasing sand depth implies that the disturbance was not caused by a double impulse of the hammer on the piston, in which case the disturbances would travel at the same velocity. The difference between the arrival times of the precursor and consolidation phase may be used to approximately calculate their relative velocity. The data used are obtained from Figures 3, 4, 5 and 6 which correspond to separate experiments. The relative wave velocities so obtained are 885, 1100, 1050, and 895 ft/sec. The relative velocity is here defined as the distance between the point of application of the pulse and the pickup, divided by the difference of the arrival times between the precursor and consolidation phase.

When modeling clay was used instead of the sand, a precursor wave was not detected (see Fig. 7 and 8). This implies that the precursor wave is not produced by the instrumentation or the method of applying the impulse.

CONCLUDING REMARKS

(1) There is considerable energy dissipation associated with dynamic consolidation produced by a pulse imparted to dry sand.

(2) The consolidation produced by repeated impacts applied by a hammer release with a fixed potential energy progresses from the source of the impact into the medium.

(3) The energy dissipated by sand confined in a tube, on successive impacts applied by a hammer released with a fixed potential energy, has been accurately measured. The results of these measurements are presented in Figure 2 which shows that the per cent energy dissipated following three or four impacts corresponding to the same level of

potential energy of the hammer, attains a constant value. The asymptotic value is attributed to the energy dissipated by intergranular friction resisting small relative displacements of the grains accompanying the visco-elastic propagation of the disturbances.

(4) A mechanism based upon physical theory governing the propagation of a disturbance imparted to unconsolidated materials is presented. From this mechanism it is inferred that a disturbance is propagated in two principal parts. One consists of a wave of small amplitude anticipating a wave of much higher amplitude propagating at a lower velocity. The first wave is called the precursor and is identified with the visco-elastic deformation of the grains. The second component carrying most of the energy is identified with dynamic consolidation. It is thus concluded that there is probably appreciable attenuation of the second wave and considerably less attenuation of the precursor wave. Further experiments were conducted to check some of these conclusions. The results of these experiments show the composite wave structure predicted from theoretical considerations. The relative velocities between the precursor and consolidation phase have been calculated from data contained in Figures 3, 4, 5 and 6 and are respectively 885, 1050, 895, and 875 ft/sec. The relative velocity is here defined as the distance traveled by the precursor and consolidation phase of the pulse, divided by the difference of their arrival times.

When the intergranular spaces are not sufficiently large to admit dynamic consolidation (grain interpenetration), a disturbance will propagate as an acoustical wave attenuated by the intergranular friction forces accompanying grain deformation. Under these conditions, the granular material will behave visco-elastically and can probably be well represented, mathematically by a Kelvin material.

Whether or not dynamic consolidation to which the precursor phenomenon is here attributed occurs in practice depends upon the initial consolidation of the material and the intensity and magnitude of the disturbance. This observation is supported by the results of the first set of experiments described in this paper.

Absolute Age of Early Precambrian Rocks in the Bighorn Basin of Wyoming and Montana, and Southeastern Manitoba*

P. W. GAST, J. L. KULP, AND L. E. LONG

Abstract—Age determinations on nine samples from the southeastern part of the Beartooth Range, Montana, indicate that the absolute age of the pegmatites and granitic gneisses of this area is 2750 ± 150 m y. A single determination from the northern Bighorn Mountains, Wyoming, suggests a similar age for this portion of the Precambrian basement. Several samples from the Winnipeg River – Johnston Lake area of Manitoba indicate an absolute age of 2650 ± 150 m y for both the pegmatites and gneisses. A similar age was found for a muscovite from the northwestern angle region of Minnesota. Rubidium-strontium ages were found to be more consistent than potassium-argon ages. Argon loss from micas was commonly as great as 15 pct.

Introduction—The measurement of absolute geologic time is necessary in order to define Precambrian Earth history. The recent development of the potassium-argon and rubidium-strontium methods of geochronometry extends the possibilities of measuring absolute ages to a wide variety of igneous and metamorphic rocks. Parts of two presumably early Precambrian areas, the Beartooth uplift of Wyoming and Montana and the Winnipeg River area of southeast Manitoba, were examined using these methods.

This investigation had two objectives: to determine the absolute age of these very ancient areas, and to investigate the magnitude of the natural variations that occur in the apparent ages derived from the A^{40}/K^{40} and Sr^{87}/Rb^{87} ratios.

Symbolically the decay of a given parent to a given daughter isotope can be denoted as follows

$$P_i \xrightarrow{\lambda_i} D_i$$

where λ_i is the decay constant governing the rate at which parent P_i decays to daughter D_i. The age of any geologic system such as a mineral can be determined from D_i/P_i and λ_i, provided the system has been closed to P_i and D_i during its history. Thus, aside from the experimentally determined concentrations of D_i and P_i and the value of λ_i, the assumption that the system is closed must be evaluated.

Unfortunately, no independent criteria to test the assumption of a closed system are available at the present time. The best evidence for this assumption is the agreement of ages determined both on different minerals and by different decay schemes. Thus provided correct decay constants are used, agreement of potassium-argon and rubidium-strontium ages may be interpreted as evidence for a closed chemical system during the history of the mineral. The agreement of ages determined on several minerals from the same geologic unit, varying in grain size and mode of occurrence, is also evidence for the assumption of a closed system. The latter test seems more reliable if a process such as continuous diffusion at room temperature is suspected. Both of these criteria are applied in this study.

In accordance with general usage the term 'age' or 'apparent age' is used for the quantity calculated from a given ratio of D_i/P_i; while 'true age' or 'absolute age' is used to designate the actual period of time which has elapsed since formation of a mineral or rock.

Decay constants—In principle the decay constant of any radioactive isotope can be determined by a direct measurement of the specific activity of that isotope. In the case of U^{238} and U^{235} these constants are known with an accuracy of about 0.5 pct and 2 pct respectively [*Kovarik* and *Adams*, 1941, 1955; *Fleming* and others, 1952]. The values of $\lambda^{238} = 0.154 \times 10^{-10}$ yr^{-1} and $\lambda^{235} = 0.972 \times 10^{-10}$ yr^{-1} are used here.

Measurements of the decay constants of K^{40} have been summarized by *Endt* and *Kluyver* [1954], *Carr* and others [1956], and *Wetherill* [1957]. The average specific activities derived from the first two summaries are 3.4 γ/gm sec, 27.6 β/gm sec; and 3.33 γ/gm sec, 28.6 β/gm sec. *Wetherill* and others [1956] have given a specific gamma activity of 3.24 γ/gm sec derived from A^{40}/K^{40} ratios determined on micas whose age was known independently from lead/uranium ratios on associated uraninites. *McNair* and others [1956] report a value of 3.41 ± 0.06 γ/gm sec and 27.6 β/gm sec. *Wetherill* [1957] reports a value of 3.39 ± 0.15 γ/gm sec. A value of $\lambda_e = 0.58 \times 10^{-10}$ yr^{-1}, based on 3.4 γ/gm sec is used here. The specific beta decay rate is also arbitrarily taken as 28 β/gm sec giving $\lambda_\beta = 4.8 \times 10^{-10}$ yr^{-1}. The abundance of K^{40} is taken as 0.0119 [*Nier*, 1950a].

* Contribution No. 280 of the Lamont Geological Observatory.

Wetherill and others [1956] have shown that for most of geologic time A^{40}/K^{40} ages are more sensitive to λ_e than λ_β. In the age range studied here the uncertainty in the age is 0.4 of that in λ_β and 0.6 of that in λ_e. By a similar argument the uncertainty in the age is approximately half of that in the A^{40}/K^{40} ratio.

Measurements of the specific decay rate of Rb^{87} are summarized by *Flinta* and *Eklund* [1954], and *Ahrens* [1956]. A number of these determinations consistently agree with a half life of about 6.0×10^{10} yr. *Bähnish* and others [1952] suggest that the use of incorrect decay schemes and poor estimates of absorption corrections made this agreement more apparent than real. They indicate that the true half life probably is significantly lower than 6.0×10^{10} yr. *Bähnish* and *Huster* [1954] and *Huster* [1955] report a new determination of the specific activity of Rb^{87}, giving a half life of 4.3 $\pm$ 0.3 $\times 10^{10}$ yr. In a more refined determination Huster and Rausch are reported [*Aldrich* and others, 1956c] to have obtained 4.95×10^{-10} yr. This concurs with the value of 5.0×10^{10} yr derived from a comparison of Sr^{87}/Rb^{87} ratios measured on micas cogenetic with uraninites giving concordant Pb^{206}/U^{238} and Pb^{207}/U^{235} ages [*Aldrich* and others, 1956c]. The corresponding decay constant is 1.39×10^{-11} yr^{-1} which is used in this paper.

The isotopic composition of rubidium reported by *Nier* [1950b] (Rb^{87} = 27.8 pct) is used in this paper.

Experimental techniques—The method of stable isotope dilution was used throughout the present investigation. This technique has been described in a general way by *Inghram* [1954]. *Aldrich* and others [1956a] have described specific techniques for age determinations. The method employed for A^{40} determinations has been described by *Carr* and *Kulp* [1957]. Analyses of strontium, rubidium, and potassium were made on single samples. A tracer consisting of 83.4 pct Sr^{86} was used to determine strontium; 94.6 pct Rb^{87} was used for rubidium analyses; and 99.2 pct K^{41} was employed in potassium analyses. The tracer solutions were calibrated in two ways [*Inghram*, 1954, p. 86]. A first calibration was performed by weighing out known amounts of the tracer salt, for example, Sr^{86} CO$_3$. From the weight, the purity of the salt and the volume of the tracer solution, the concentration of the tracer could be found. A second calibration was performed by adding a known volume of tracer solution to a known amount of a reagent grade salt of the corresponding element (for example, potassium phthalate is used in the calibration of the K^{41} tracer). This mixture was analyzed isotopically. The tracer concentration can then be found from the isotope ratio, the amount of pure salt and the volume of tracer solution used. These calibrations concurred within two per cent with one exception. The concentration of the tracer solutions is thought to be accurate within three per cent. Rubidium and potassium analyses were made on two or five per cent aliquots of the total sample solution.

All mass spectrometric analyses were made on a first order direction focusing, 60° sector field, six-inch radius of curvature mass spectrometer. An ion source similar to that of *Aldrich* and others [1953] was employed. Five to 20 micrograms of strontium oxide derived from strontium perchlorate on a tantalum filament served as a source of Sr^{+} ions. Potassium and rubidium were analyzed together on a tantalum filament previously checked for K and Rb background. In general, isotope ratios could be measured with a standard deviation of less than one per cent.

Discussion of analytical data—A complete summary of analytical data including all replicate measurements is given in Tables 1 and 2. In addition to the concentration of rubidium, normal strontium, radiogenic strontium and potassium, sample weights and isotope ratios needed for age calculations are given. Petrographic, geologic and geographic descriptions of samples are given in the Appendix.

The error on individual concentrations arises from two sources, the mass spectrometric analyses and manipulations involved in the chemical processing of the sample (for example, taking aliquots, adding tracers). The error caused by mass spectrometric analyses is predominant over other errors because it is not directly proportional to the error in the isotope ratio. If A is defined as the total amount of the unknown constituent in the sample, S is defined as the total amount of tracer, and R is taken as the ratio of the tracer isotope to a given sample isotope, it can be shown that $(\partial A/A)/(\partial R/R)$ is usually greater than unity while $(\partial A/A)/(\partial S/S)$ is always unity. The random

error arising from measurement of tracer and aliquot volume is taken as one per cent. Errors in the isotope ratio were also taken as one per cent except in a few poor runs where somewhat higher values up to 1.6 pct were assigned. Using these individual errors, the error on the concentration is found from

$$\frac{dA}{A} = \sqrt{\left(\frac{\partial A/A}{\partial R/R}\,\frac{dR}{R}\right)^2 + \left(\frac{dS}{S}\right)^2}$$

For the analyses reported here $(\partial A/A)/(\partial R/R)$ varied from 2.6 to 1.2.

Another estimate of the variance of a single measurement comes from replicate analyses made under identical conditions. The validity of this estimate depends on the number of replicates and the extent to which identical conditions have been maintained. Using the duplicate rubidium analyses given in Table 1 in addition to some taken from unpublished work on the rubidium content of igneous rocks, a standard deviation of 2.0 pct is found. This is in good agreement with the random error found from individual sources of error.

Both the normal strontium concentration and the radiogenic strontium concentration are given in Table 1. The normal strontium in pegmatitic minerals is found to be quite low, especially in the micas. Micas from igneous and metamorphic rocks have a somewhat higher normal strontium content.

Two sources of uncertainty, contamination and errors in isotope ratio, contribute most to errors in the true normal strontium content; both increase sharply in relative magnitude for very low concen-

trations. Because strontium introduced as contamination during processing and normal strontium occurring in the mineral lattice are probably indistinguishable, such contamination has no effect on the concentration of radiogenic strontium. Obviously, if the ratio of radiogenic to normal strontium is high (for example, GmX-10 lepidolite) the uncertainty in the normal strontium has no effect on the radiogenic strontium concentration.

The isotopic composition assumed for the normal strontium, specifically the Sr^{87} abundance, is important in samples having a high normal strontium content. If X is taken as the amount of radiogenic strontium and Y represents the natural isotope abundance of Sr^{87}, this effect is given by $(\partial X/X)/(\partial Y/Y)$. In terms of radiogenic and normal strontium, the differential

$$\frac{\partial X/X}{\partial Y/Y} = -(A/X)Y$$

where A is the amount of normal strontium. The value of Y is very close to 0.07, thus the ratio of normal to radiogenic strontium must be greater than 14 before a one per cent error in isotopic abundance of Sr^{87} results in one per cent error in radiogenic strontium concentration. Actually, the variations found in natural strontium are quite small [*Gast*, 1955, 1956, and further unpublished work]. These studies indicate that the initial isotopic abundance of Sr^{87} in granites and granite pegmatites probably does not vary more than three per cent over the last 3.0 b y. It is concluded that variation in the isotopic composition of the non-radiogenic strontium of the mineral is not an important source of error where radiogenic strontium is greater than 25 pct of common strontium. In the present study all except one sample, that is, microcline, GmYB-12, where radiogenic strontium is 8.5 pct of normal strontium, meet this condition.

The uncertainties given for radiogenic strontium content are then due to the same causes as those in rubidium concentrations. The error in concentrations, due to mass spectrometric analysis, is found from the coefficient $(\partial X/X)/(\partial R/R)$ and the uncertainty in the isotope ratio dS/S is again estimated at one per cent. The error given for the ratio of daughter strontium over parent rubidium is combined from previous errors using the equation

$$\frac{A \pm a}{B \pm b} = \frac{A}{B} \pm \sqrt{\left(\frac{a}{A}\right)^2 + \left(\frac{b}{B}\right)^2}$$

Note that the ratio radiogenic strontium (Sr^{87})/radioactive rubidium (Rb^{87}) is completely independent of sampling variations since these isotopes were determined on the same sample. Errors in potassium analysis are found in the same way as rubidium errors are derived. They are somewhat higher both because the isotope ratios are usually based on fewer scans and because the coefficient $(\partial A/A)/(\partial R/R)$ is often quite high.

The error given on the A^{40} concentrations is derived from replicate analyses made over a period of two years. This experience indicates that the standard deviation for the argon concentrations is from two to four per cent depending on the amount of argon present.

The error in the A^{40}/K^{40} ratio is derived like that in the Sr^{87}/Rb^{87} ratio.

The ages derived from these ratios are given in Tables 3 and 4. When more than one analysis on a given sample was available, the error in the age was diminished by $1/\sqrt{K}$ where K denotes the number of replicate analyses.

Discussion—The interpretation and relation of the ages determined in this study to the geologic history of the two areas of ancient rocks will be discussed separately. Absolute ages determined by other methods or workers will be reviewed when they are pertinent.

Bighorn Basin area—The geology of the metamorphic and igneous complex of rocks surrounding the Bighorn Basin has been a subject for more or less continuous field work over the last 50 years [*Darton*, 1906]. Much of this work has been particularly directed at an understanding of the structural features of this rim: see for example, *Bucher* and others [1934], *Chamberlain* [1940], *Thom* [1944, 1947, 1955], *Demorest* [1941], and *Fanshawe* [1939]. These studies were of necessity concerned with events taking place mostly in Laramide Time. *Cloos* and *Cloos* [1934] first suggested that in a broad way, Laramide structures may reflect Precambrian structural trends. Later work seems to support their suggestion [*Lammers*, 1939]. However, it has not been until the recent work of *Eckelmann* and *Poldervaart* [1957] that some of the geologic events of the Precambrian history have been defined. Their detailed study of the Quad Creek area in the Beartooth Mountains suggests the following sequence of events: (1) deposition of an ancient sedimentary sequence; (2) emplacement of gabbro and ultramafic intrusions followed by folding; (3) regional metamorphism and granitization accompanied by pegmatite intrusion and later basaltic dikes; (4) later Precambrian dolerite dikes; and finally, the later Paleozoic and Laramide history referred to above.

The absolute age determinations reported here were made so that Precambrian history described here could be correlated with ancient events evident in other isolated occurrences of Precambrian basement in this area, such as the Bighorn, Wind River, and Owl Creek-Bridger uplifts, and the Cherry Creek and Pony gneisses seen in southwestern Montana.

Previous age determinations from the Bighorn Basin area utilizing radioactive decay have been birefly reviewed by *Eckelmann* and *Poldervaart* [1957]. *Goodman* and *Evans* [1941], report several measurements of the helium index on the Quad Creek norite, giving an age of 1300–1900 m y. Later work on the helium index by *Keevil* [1941] however, has shown that such measurements are

not reliable as absolute ages. This earliest work established that these rocks were early Precambrian but absolute values could not be assigned.

Aldrich and others [1955] and *Wetherill* [1955] have measured some ages on a lepidolite in the Wind River Canyon area. They obtain a rubidium-strontium age of 2460 m y and a potassium-argon age of 2290 m y using the decay constants adopted in this paper.

Table 3 summarizes new age determinations reported in this paper. In addition to the rubidium-strontium and potassium-argon ages measured on micas and feldspars, isotopic ages of a uraninite from a sodic pegmatite ten miles south of Cooke City, Montana, are reported. The agreement among these ages is within experimental error. The pattern is, however, similar to that typically found for uraninites. Assuming that this pattern is due to lead loss the Pb^{207}/Pb^{206} age is closest to the true age. This age is also in best agreement with the rubidium-strontium ages. In any event the absolute age derived from the uraninite and the average rubidium-strontium age are in agreement due to the uncertainty in the Rb^{87} half life.

Specific geographic locations of different areas in which absolute age measurements have been made are shown in Figure 1. Of the four different locations shown on Figure 1 the most detailed study has been in the Beartooth Mountains, particularly in the Quad Creek and Gardner Lake areas. This area was chosen because of the full information available on the geologic environment. *Eckelmann* and *Poldervaart* [1957] have studied the pegmatites in the Quad Creek area and conclude that they are probably synchronous with the regional metamorphism producing the granite. *Harris* [in preparation] has studied the Christmas Lake and Blackstone Lake pegmatites and also concludes that they are probably synchronous with the regional metamorphism. The agreement of the rubidium-strontium age found for the gneissic granite Gsm YB-17 with the pegmatite ages supports this conclusion. It is concluded that the ages reported here represent a single geologic event,

namely, that of the major regional metamorphism and granitization at about 2750 m y ago.

The measurements given in Table 3 show a high degree of concurrence. Several regularities are evident. First, the potassium-argon ages are consistently lower than the rubidium-strontium ages measured on the same mineral. The differences between the two ages remain rather constant. The explanation of these differences is quite probably some loss of argon from these minerals. With the exception of biotite Gm YB-5 all rubidium-strontium ages measured here agree within the experimental error. Perhaps it is significant that the pegmatite from which this biotite came occurs in a zone of alteration. The biotite sample is within 200 ft of a strongly altered portion of norite. Alteration of the biotite associated with the alteration of the norite seems the most plausible explanation of the low age. The agreement of the other measurements on feldspar and uraninite representing several mineral species, supports the conclusion that the Sr^{87}/Rb^{87} ratio in the muscovite and microcline samples is essentially undisturbed. The possibility of minor alteration such as the loss of one per cent of radiogenic strontium cannot be discounted. Indeed, the possibility of such loses may make the uncertainty in the true age somewhat skewed toward higher ages. The average of seven rubidium-strontium ages is 2750 m y with a standard deviation of 30 m y. Considering possible sources of systematic error and uncertainty in the Rb^{87} half life, the absolute age of the pegmatites and metamorphic rocks must be in the range of 2600 to 2900 m y. However, the relative ages between this and other areas are known more accurately.

Winnipeg River – Johnston Lake area, southeastern Manitoba—During the summer of 1956 a detailed mapping program of the Rice Lake group around the Huron and Silverleaf Claims was begun under the direction of F. D. Eckelmann. It was initiated in part because of the very ancient ages reported by *Nier* and others [1941], *Cummings* and others [1955], *Davis* and *Aldrich* [1953]. A fairly detailed geochronologic study has accompanied the petrologic investigation. The geographic and geologic setting of the area is seen in Figure 2. This map is a portion of the Cat Lake – Winnipeg River map area consisting of metabasalts and metasediments, gneissic granites intruded by pegmatites, and pegmatitic granites. Foliation trends generally ENE. The Silverleaf pegmatite has been described by *Stockwell* [1932]. It is a large-zoned complex pegmatite at least 500 ft long and about 100 ft wide. Lepidolite is found in a core surrounded by quartz and spodumene. It is intruded into a metamorphosed sequence of pillow lavas.

The detailed study of the Winnipeg River – Johnston Lake area (Eckelmann, personal communication) suggests a metamorphic origin for the granite rocks and granite pegmatites of the area. Thus, the age measured here is probably the date of this regional metamorphism. Details of the study leading to this conclusion will be published at a later date.

The three specific locations of samples studied here are shown in Figure 2. They are (1) the Silverleaf pegmatite, (2) a small pegmatite at the contact of the amphibolite and albite granite gneiss, and (3) a sample of biotite granitic gneiss from the migmatite zone. The apparent ages from the present study plus previously reported potassium-argon and rubidium-strontium ages have been summarized in Table 4. The ages reported by *Stevens* and *Shillibeer* [1956] have been recalculated for the decay constants adopted here.

The potassium-argon ages from this area are seen to be consistently lower than the rubidium-strontium dates and furthermore, show a rather large variation even for micas. This discrepancy is interpreted to be due to loss of argon from these minerals. The apparent argon retention of micas ranges from about 70 pct for the Huron Claim muscovite to about 90 pct for lepidolite GmX-10, assuming the true age is 2650 m y. Rubidium-strontium ages on the two different lepidolite samples and one muscovite reported here are in remarkably good agreement. The age reported by *Aldrich* and others [1955] further supports this agreement. The weighted average for these four samples is 2650 m y. The consistency of these

four samples which come from at least three different immediate geologic environments suggests that this represents the undisturbed Sr^{87}/Rb^{87} ratio. The rubidium-strontium ages of microcline from the Silverleaf Claim and of biotite separated from a granite gneiss are significantly lower. These are apparently cases of Sr^{87} loss; the mineral structure and grain size are both factors in a possible explanation of these discordant ages.

The uranium-lead ages on uraninites and monazite from the Huron Claim pegmatite also show quite general discordance [*Nier* and others, 1941]. *Eckelmann* and *Kulp* [1957] have discussed various theories put forth to explain this discordance and conclude that the Pb^{207}/Pb^{206} age is probably minimal due to lead loss in the latter third of the history of the mineral and suggest a probable age close to 2650 m y. The ages found here support the conclusion of lead removal. *Wetherill* [1956] has discussed the problem of open mineral systems and has derived a graphical scheme for finding the time when lead was removed from a uranium mineral. Assuming 2650 m y as the correct age, both uraninites for which complete isotopic data are available suggest that the event resulting in the discordant ages took place 500 m y ago. A general temperature rise in this area at that time is a possible explanation of both the discordant uraninite dates and the apparently low potassium-argon and rubidium-strontium dates discussed below. The importance of detail in geochronologic studies of Archean areas such as this should be emphasized. It is only the variety of minerals and number of samples which give some confidence in the apparent ages found for the area. The rubidium-strontium age appears most trustworthy. The data reviewed here indicate that the true age of the emplacement of the pegmatites in this area is 2650 ± 150 m y. The single determination on the country rock suggests that the surrounding granites and gneisses are contemporaneous with the pegmatites.

The single measurement on a sample of muscovite from a pegmatite in the Northwest Angle region of Minnesota shows that the ancient metamorphic event extended farther to the south. Goldich (personal communication) reports an A^{40}/K^{40} ratio of 0.311 for this sample. This gives an age of 2.51 b y using the decay constants assumed here. The magnitude of the apparent rubidium-strontium is in good agreement with those found in the Winnipeg River – Johnston Lake area. The ratio of the potassium-argon to the rubidium-strontium ages in both localities is also similar. The consistent disagreement between potassium-argon and rubidium-strontium dates suggests some of the potassium-argon dates of 2.4 to 2.5 b y reported by *Goldich* and others [1957] for other rocks in Minnesota could represent rock-forming events which actually occurred 2.6–2.7 b y ago. The Vermilion Range granites and granites as far south as the Minnesota River valley (Sacred Heart granite, Morton gneiss) may then be identical in age with the Laurentian granite gneisses of the Winnipeg River area.

Comparison of Bighorn and Winnipeg River areas—One of the ultimate goals of geochronology is the correlation of geologic events in widely separated Precambrian areas. Such correlations are difficult and often tenuous when based on field studies alone. The geochronologic studies on these two areas present an excellent example for possible correlation of very ancient events. In this regard, it is emphasized that systematic errors such as errors in Rb^{87} half life and possible errors in tracer concentrations are not important when similar ratios, such as Sr^{87}/Rb^{87}, measured under similar conditions, are compared. The average Sr^{87}/Rb^{87} ratio found for concordant samples in the Bighorn Basin area is 0.0389 ± 0.0004, as compared to 0.0377 ± 0.0004 in the Manitoba area. Making the assumption that these samples giving rubidium-strontium ages agreeing within experimental error, represent the true age, the difference between these two corresponds to a time interval of 90 m y, indicating that the basement rocks in the Bighorn-Beartooth area are older than those in southeastern Manitoba and Minnesota. Statistical comparison of the data from these two areas suggests that this difference is real. The probability of the apparent age being the same is less than 0.1. Thus if the assumption regarding the true age is granted, these data suggest that two chronologically distinct events may be involved in these areas.

Comparison of potassium-argon and rubidium-strontium—Comparison of the ages given here shows that quite generally the potassium-argon ages are lower than the rubidium-strontium ages. Comparing only those samples which give apparently correct rubidium-strontium ages, it is found that the potassium-argon ages are about nine per cent lower than the rubidium-strontium ages. The difference is somewhat greater than that reported by other workers for example, *Wetherill* and others [1956]; *Wasserburg* and others [1956]. This is in part due to the decay constants adopted here. However, even if the constants adopted by *Wetherill* and others [1956] are used, the potassium-argon ages are only increased by three per cent;

thus the apparently low potassium-argon ages cannot be completely explained as a result of different decay constants. Three apparently low rubidium-strontium dates were also found. Two of these (GsmX-12 biotite and GmX-1 microcline) are from the southeastern Manitoba region. Along with the discordant uranium-lead dates found at the Huron Claim the discordant potassium-argon and rubidium-strontium ages suggest that this area may have been subject to a later event resulting in these disturbed ages.

The agreement of the Bighorn samples is somewhat better, although very real differences between the potassium-argon and rubidium-strontium ages suggesting argon loss are seen. It seems likely that at least in part this loss of argon may be due to the plutonic or orogenic activity to which this area was subject in late Mesozoic and early Cenozoic time.

The low potassium-argon ages suggest that loss of argon from micas may be more frequent and greater than earlier work has suggested. They further indicate that potassium-argon ages from such old terranes may be subject to severe limitations. They may quite generally be minimum ages. In order to establish absolute ages it appears necessary to compare different mineral systems by the same method as well as using two different methods.

Conclusions—The specific conclusions of this study may be summarized as follows:

(1) The natural variation of most of the Sr^{87}/Rb^{87} ratios measured here is comparable to or less than the experimental variation. Seven out of eight samples from the Bighorn Basin region fall within a range of 3.6 pct, four out of six samples from Manitoba and Minnesota fall within a range of 1.5 pct.

(2) In sharp contrast, the A^{40}/K^{40} ratios vary outside the experimental error. Four samples giving Sr^{87}/Rb^{87} ratios concurring within 3.6 pct give A^{40}/K^{40} ratios varying by 14 pct. This is more than twice the analytical variance. The argon loss of old pegmatitic micas is commonly as high as 15 pct in the two regions studied here.

(3) The absolute age of the major regional metamorphism in the rocks of the Beartooth Mountains of Wyoming and Montana is 2750 ± 150 m y. A single determination in the northern Bighorn Mountains suggests a similar age for these rocks.

(4) The absolute age of the pegmatites and granitic gneisses of the Winnipeg River region of southeastern Manitoba is 2650 ± 150 m y. A single rubidium-strontium determination on a muscovite from the northwestern angle region of Minnesota and the potassium-argon ages of *Goldich* and others [1957], suggest that rocks of this same age may extend well down into Minnesota.

Acknowledgments—The authors are indebted to several people for assistance in experimental work. Olavi Kouvo assisted in the preparation of many samples and his help in separation of minerals was essential to major portions of work reported here. F. Bazan, W. Barringer, and E. Catanzaro assisted in various phases of chemical preparation, vacuum fusion and isotopic analysis. Construction of the mass spectrometer was greatly facilitated by the excellent machine work of W. T. Tamminga and M. A. Gwinner, and advice on electronic components of R. D. Janes. The authors are indebted to J. Cobb for chemical and isotopic analyses of uraninite reported in Table 2.

The senior author acknowledges that he learned many of the techniques employed here during his association with L. T. Aldrich, G. W. Wetherill, G. L. Davis, and G. R. Tilton of the Carnegie Institution of Washington while a Fellow at the Department of Terrestrial Magnetism.

A. Poldervaart, F. D. Eckelmann, and R. L. Harris provided samples and freely advised the authors on the geology of the areas studied. Discussions with W. S. Broecker, P. E. Damon, and B. J. Giletti were also helpful.

Financial assistance was provided by the Research Corporation and the Division of Research of the Atomic Energy Commission under Contracts At(930-1)-1114 and AT(30-1)-1669. Enriched stable isotopes used in this research were supplied by the Stable Isotopes Research and Production Division, Oak Ridge National Laboratory, and the Atomic Energy Research Establishment, Harwell, England.

Appendix—Description of Samples

Gm YB-11 (*LA-11*)—Muscovite from zoned pegmatite near Christmas Lake in the Beartooth Mountains. Exact location of sample is given by *Harris* [in preparation] in the description of this area. The pegmatite is about 100 ft long and 10 ft wide and is essentially conformable. A single book of white muscovite about two inches across was chosen for analysis. Two rectangular pieces 1 × 3 cm were cut from the center of this book. These in turn were cut in half, giving cubes about 1 cm on a side. Two separate analyses were made on two such cubes. Separate argon and potassium analyses were made on quartered samples taken from a batch of muscovite.

Gm YB-12 (*LA-12*)—Tan-gray microcline with a few perthite lamellae from the same pegmatite as Gm YB-11, with no visible inclusions, rather fine exsolution lamellae (0.5 mm). Microscopic examination of powder showed a few large quartz grains.

Gm YB5- (*LA-5*)—Biotite from a small discordant pegmatite within the Quad Creek metanorite. Sample was collected along a roadcut about 500 ft south of the northern intersection of Route 12 and the norite body (see map of *Eckelmann* and *Poldervaart* [1957]). Sample consisted of small intergrown books, the largest plates being no more than a few centimeters across. Some books were closely intergrown with plagioclase. Many surfaces showed a dull light green staining, probably due to chloritization, and some rust colored staining on shiny black mica. Sample taken for analysis was cut from plates chosen for a minimum of staining. However, material analyzed still contained dull and stained surfaces.

Gm YB-6 (*LA-6*)—Pink microcline with some perthite lamellae also from a pegmatite with the Quad Creek metanorite, about 200 ft to the southwest of the biotite pegmatite. Sample has no visible intergrowths. Exsolution lamellae are fractions of a mm in width.

Gm YB-16—Muscovite from discordant pegmatite ½ mile south of Blackstone Lake. Exact location of this pegmatite is given by *Harris* [in preparation]. The pegmatite is unusual for this area in that it contains beryl crystals up to 10 inches long. A single book of muscovite about 4.5 inches across and about 4 inches thick was collected. Samples analyzed came from a part of this book about ¾ of an inch thick. Individual sheets of mica could be peeled from this book. These sheets were partly iron-stained but had regular areas where they were perfectly clear. These clear areas were cut out with a scissors and cut in pieces smaller than 2 cm^2. An 8-gram sample of such material was divided in half. One half was taken for argon analysis. Sample for rubidium analysis was quartered from the remaining half. Sample was collected by Rae L. Harris.

Gsm YB-17(*Z-7*)—Biotite separated from biotite gneiss collected from roadcut on Highway 12 southwest of Frozen Lake. Exact location shown on map of *Harris* [in preparation]. Gneiss contains microcline porphyroblasts up to 2 cm across. Modal analysis showed 33 pct quartz, 20 pct microcline, 41 pct plagioclase, and 5 pct biotite. Biotite shows no evidence of chloritization. Sample analyzed contained more than 95 pct biotite. Description and separation of this sample are the work of R. L. Harris, Dept. Geology, Columbia University.

Uraninite K-156—Collected by A. Poldervaart from an albite, quartz, biotite pegmatite about one mile north of the crossing of Clarks Fork and U. S. 12. This pegmatite surrounds a remnant of amphibolite and is in turn surrounded by granitic gneiss. A small chip weighing about 20 milligrams was selected for analysis.

All of the above samples from the Beartooth Plateau were furnished by A. Poldervaart, Dept. of Geology, Columbia University. Sample numbers in parentheses are those used by *Eckelmann* and *Poldervaart* [1957] and *Harris* (in preparation).

Gm YB-19—Biotite from biotite rich vein in pegmatite. Collected about 500 ft west of Cody Dam in Shoshone Gorge. Biotite was separated from rock using bromoform, individual flakes ranged from 1 to 2 mm across to small fractions of a mm. The sample analyzed was greater than 95 pct mica.

Gsm YB-20—Biotite from a very coarse-grained gneiss, consisting mainly of plagioclase, microcline, quartz, biotite, and hornblende. Several large pieces of this rock were collected from a roadcut along U. S. 14. Approximate location is about the position of the "U. S." on *Osterwald*'s [1955] base map. The rock contained very large porphyroblasts of microcline, some of them over one inch across, and could be described as an augen gneiss. Biotite flakes ranged up to 2 or 3 mm across. Biotite was separated first using heavy liquid techniques (bromoform), then sieving out the fine fraction and finally magnetically using Frantz Isodynamic Separator. The final separate was greater than 95 pct pure biotite, the primary impurities being chlorite and hornblende. The biotite is greenish brown in color.

Gm X-10—Lepidolite from along Winnipeg River, southeastern Manitoba. This sample was taken from a dump at the end of an abandoned tramway from the Silverleaf Claim (now called Bear Claim). Exact location is shown in Figure 2. The sample is identical to new material recently blasted from the claim area. The sample is typical dark lilac-colored, coarse and massive, with individual plates of mica usually 2 to 3 mm across. Some veins of albite were present. Sample for analysis was crushed on an alumina buckboard and muller, then settled in bromoform to remove feldspar and quartz. Only early settling coarse fractions were taken.

Gm X-2—Lepidolite from prospect pit on Silverleaf Claim, southeastern Manitoba. Sample consisted of fine grains of purple lepidolite heterogeneously dispersed through massive dark gray quartz. Several pounds were crushed to about 60 mesh in a jaw crusher and disc pulverizer. Lepidolite was then separated by settling in bromoform. Coarse material sinking in a few minutes was taken for analysis.

Gm X-1—Salmon-colored perthitic microcline, collected from same pit as Gm X-2 lepidolite. Single crystal about 6 inches long was collected. Exsolution lamellae were less than 0.2 mm wide. Several thin veins of white albite cut through the crystal.

Gm X-11—Muscovite collected from quartz-microcline pegmatite about 1500 feet northeast of Huron Claim. This pegmatite is at the contact of a white pegmatitic granite gneiss and metabasaltic pillow lava. The pegmatite is from 5 to 10 ft wide and about 40 ft long. It has both sharply discordant and permeation contacts with the granite gneiss indicating essentially synchronous emplacement of gneissic granite and pegmatite. Sample consists of curved plates of a white mica having a slight metallic luster. Individual books were no more than one cm across. Sample taken for analysis was crushed lightly on an alumina buckboard and muller and sieved to coarser than 60 mesh. The remaining coarse material ranged up to pieces a half cm across.

Gsm X-12—Biotite from a medium- to coarse-grained plagioclase-biotite-hornblende gneiss. Rock specimen is from a lens-shaped gneiss area within a migmatic sequence. The gneiss grades into the migmatite both along and across strike. Such lenses are common in this area. Location of specimen is given in Figure 2. Thin section shows biotite predominating over hornblende, that is, probably growing at the expense of hornblende. Biotite along with other magnetic minerals was separated on a Carpco magnetic separator. Biotite was then separated from other minerals on a Sutton, Steele and Steele Whippet Air Shaking Table. Microscopic examination showed about two to three per cent quartz and feldspar grains and some hornblende. Olive-green biotite makes up more than 95 pct of the sample.

Samples Gm X-2 and Gm X-1 were collected by one of the authors (J. L. K.) during the summer of 1954. The remaining Manitoba samples were furnished by

F. D. Eckelmann, who collected them in the summer of 1956.

Gm X-15—This sample was furnished by S. S. Goldich, Dept. of Geology, University of Minnesota. It consists of small books of white muscovite up to one cm across, and was analyzed as received.

Discussion of "Evidence for a Critical Wind Velocity for Air-Sea Boundary Processes"

BY HUGO MANDELBAUM

and "Change in the Relationship Between Wind and Surface Water Movement at Higher Wind Speeds"

BY A. L. LAWFORD AND V. F. C. VELEY

[*Trans.*, **37**, 685–693, 1956; **38**, 584–586, 1957]

Hugo Mandelbaum (Wayne State University, Detroit, Michigan; Author's closure)—The discussion by Lawford and Veley centers on the evaluation of the current velocity calculated for wind force 4. By disregarding this value, they point out, a smooth curve could be drawn through all other points (Fig. 5). A similar view was expressed by G. Verploegh in a letter to the author. Verploegh points out that the exceptional value at force 4 appears exceptional only in its *NE*-component. He has plotted the values of Table 4, columns 3, 4, and 10 (Fig. 6). The curves for the *NW*-components and the current directions show a smooth variation. By replacing the exceptional value 10 cm/sec by 8 cm/sec to smooth out the curve of the *NE*-components, we would arrive at 7 cm/sec for the resultant current velocity. This value fits well into the curve drawn by Lawford and Veley (Fig. 5).

Verploegh suggests that the large deviation of the *NE*-component at force 4 may not have a physical cause but might result from a computational error "that unfortunately slipped in somewhere." Lawford and Veley suggest it might be caused by a variation within the statistical material, namely, by a preponderance of winds from the SSW sector which produce stronger currents.

I had not suspected the value at force 4 when I drew the conclusions as presented in my paper. In a statistical investigation we should not discriminate one value against others, unless we want to concede that a statistical approach is futile. A computational error is very unlikely, as a look into Table 3 will show. The values of most NE-components are consistently higher at force 4 than at 5. It is unlikely that computational errors should be so frequent and consistently in the same direction. Unfortunately the punch cards of the original data are at present sorted for a different project, so that it is difficult now to determine how many observations at SSW, SW, and WSW winds were used for the analysis at each wind force. Figure 6b as plotted by Verploegh might suggest a change in wind direction. It shows that at forces 4 and 5 the resultant current has a more northerly direction than at lower and higher wind forces. This might indicate that at forces 4 and 5 SSW winds were more prevalent as Lawford and Veley suggest. However this argument is not conclusive. From Figure 5 of a previous paper [*Mandelbaum*, 1955] it can be seen that winds coming exclusively from the SW sector cause the same directional deviation of the current. At weak and strong winds the currents run with the wind ($\theta = 45°$), while at forces 3 and 4 the direction of the current deviates 10° to the left ($\theta = 35°$). This is a deviation similar to that shown in Figure 6b.

Nevertheless one must agree that the extraordinary value of the NE-component at Beaufort 4 as plotted by Verploegh (Fig. 6a) arouses suspicion when viewed in connection with the smooth curves of the NW-components and the direction deviations (Fig. 6). Even if we cannot give a definite explanation for the exceptional value, one would be justified in placing less statistical weight on it and drawing a curve through all other points as suggested by the discussents (Fig. 5).

Verploegh moreover points out that a discontinuity between Beaufort 4 and 5 could hardly be identical with that proposed by Munk at about 6 cm/sec. Only in the Roll scale would the break lie at this velocity. The other scales place the interval between Beaufort 4 and 5 in the neighborhood of 8 cm/sec. Considering this in connection with a lesser statistical weight put on the value for

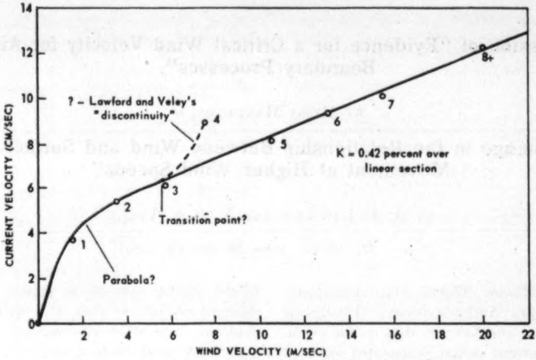

FIG. 5 – Redrafting of Mandelbaum's Figure 1 using Verploegh's scale

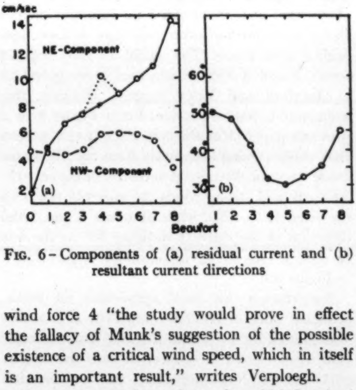

FIG. 6 – Components of (a) residual current and (b) resultant current directions

wind force 4 "the study would prove in effect the fallacy of Munk's suggestion of the possible existence of a critical wind speed, which in itself is an important result," writes Verploegh.

I have to concede another point which Lawford and Veley made, namely, the argument about the constant *c* in the equation $V = kw + c$, which would indicate the existence of a wind-induced current even at calms. The reason for retaining *c* was the following. Table 4 shows that the 'residual current at calms' still contains an influence of the wind velocity. This functional relationship was interpreted as the influence of previous wind situations which are felt more at weaker winds which change their direction more frequently. If the statistical value is still a function of the wind, the constant *c* might represent such a non-eliminated element, and the origin would not be a comparable statistical value. However, spurred by the critical remarks, I tried to find a reliable statistical value for wind force zero. I analyzed 425 observations which were made at wind situations described as calms. These were for some reason not analyzed previously. The NW- and NE-components of the resultant current at calms were found to be 4.71 cm/sec and 1.70 cm/sec respectively. Since these values closely coincide with the 'residual current at calms' for weak winds the difference representing a wind-driven current is practically zero. The origin therefore is another statistical point.

Considering this a parabola accommodates the first four points better than a straight line for all conversion scales except that of Richter. This is one point more in favor of the smooth curve suggested by Lawford and Veley and Verploegh (Fig. 5).

(Editor's note: Figure 5 was prepared by A. L. Lawford and V. F. C. Veley for publication with their discussion which appeared in the August 1957 issue of the *Transactions*, pp. 585–586. It was inadvertently omitted, and so is published here.)

Discussion of "A Criterion for Selection of Length of Record for a Moving Arithmetic Mean for Hydrologic Data"

BY ROBERT T. BEAUMONT

Trans., **38**, 198-200, 1957

T. E. A. van Hylckama (Laboratory of Climatology, Centerton, New Jersey)—The author has developed a formula "to determine length of record to use to compute a representative moving arithmetic mean to best estimate the next event." I have applied this formula to two sets of 51 random numbers taken from the tables of *Fisher* and *Yates* [1943, p. 90] with the following results:

k:	5	10	15	20	25	30	35	40
φ_1:	868	1044	967	972	1052	1342	1078	952
φ_2:	1026	1060	918	881	853	733	831	1055

From these average error mean square (AEMS) figures, it should be concluded that five 'years' is the best period to predict the next event in the first series and 30 'years' in the second. The random numbers would thus seem to possess a periodicity, but such periodicity is spurious since the numbers are random. Similarly, any apparent periodicity in comparatively short series of 50 years of records of annual streamflow or precipitation are accidental and certainly can give no clue as to the magnitude of the next event.

The fact that the data of precipitation and streamflow are random is further indicated by the individual AEMS's. The k values range from ten for Spokane, Washington, and Laramie, Wyoming, to 35 for Cheyenne, Wyoming, and to deduce from the composite graph (Fig. 4) that 20 years is the best period seems a fallacious conclusion. Moreover, whereas a correlation can usually be established between annual precipitation and streamflow, and although such correlation at times may fail due to extraordinary hot or cold seasons or unusual intensities of rainfall, it is most unlikely that even if precipitation would show a periodicity of 20 years, streamflow would show a 'best period' of 15 years.

A closer study of the AEMS formula shows that the magnitude of the AEMS is determined by the precipitation or runoff data of the last $(n - k)$ years in the observed series. If these years happen to have a small variability with a mean close to the average mean of the sets of k years, the AEMS will be small. If, on the other hand, these last years contain extremes the AEMS will be high. Since yearly precipitation data show rarely, if ever, any persistency or definite periodicity even over periods of a hundred and more years [for example, *Rosenan*, 1955; *Labrijn*, 1945; *Brooks* and *Carruthers*, 1953] the AEMS is a random number taken from random data and cannot possibly be indicative of future events.

Robert T. Beaumont (U. S. Soil Conservation Service, Portland, Oreg., Author's closure)—The analysis made by van Hylckama is most interesting and I appreciate his interest in my work. The results he obtained by using two sets of random numbers are parallel to some of my earlier efforts. However, our interpretation of results differ.

van Hylckama's syllogism that computation of the average error mean square has no value for precipitation and runoff records because its computation on two random series resulted in low values of AEMS for k equal to 5 and 30 years, overlooks one important aspect of the problem. That is to make an analogy between results computed from random numbers and results computed from physical climatic records.

van Hylckama does not make clear why a single period for k should correspond to the lowest value for AEMS when using random numbers. One would expect, and the results we have obtained to date confirm, that there is no single period for k which correspondingly has the lowest AEMS value for a random series.

There is merit in van Hylckama's comments on the composite graph (Fig. 4) for there is always some risk in interpretation of results drawn from a small population as aptly demonstrated by his conclusion from the two series of random numbers. Reference to this aspect of the problem was treated in my article (p. 199) as follows: "A great many more computations of AEMS should be made on similar climatological and hydrological data to ascertain if the 15–20 year is the best period, or whether there are other periods which give a lower AEMS. These data should be examined to see if there are other parameters by which they could be classified, (that is, climatic parameters)." Similarly, if AEMS values could be computed from a large series of random numbers, some basis for comparison and testing of the AEMS between the random numbers and the physical climatic records should evolve.

Reviews, Abstracts, and Bibliography

Reviews and Abstracts

FELIX CHAYES, *Petrographic modal analysis—An elementary statistical appraisal*, John Wiley & Sons, xii + 113 pp., 1956, $5.50.

Chayes' detailed study of the modal analysis of rocks has extended over a considerable period of time. This book contains an interpretation of his work. It is, by itself, a distinct contribution to quantitative petrography. Chayes first proves the fundamental area-volume relationship which he calls the "Delesse relation." He states it thus: "Thus, the ratio of the area occupied by mineral A to the area occupied by all minerals (the total measurement area) is a consistent estimate of the volume percentage of mineral A in the rock."

Six of the remaining chapters represent a statistical study and an interpretation of the data for a series of granites which he has carefully studied. Using these data, Chayes evaluates and describes: (a) the reproducibility of thin-section analyses; (b) identification and tabulation conventions; (c) analytical error in modal analysis; (d) effect of grain size and area of measurement on analytical error; (e) a measure of coarseness in the granitic fabric; and (f) control of analytical error by replication.

Modal analysis of banded rocks is critically examined and positive recommendations on how to handle this type of measurement are given. The "Holmes effect" concerns the overestimation of opaque minerals in transmitted light. That is, the area measured is always that of the maximum cross section in the thin section rather than the true area which is the area at the surface of the thin section. Chayes has examined this effect analytically and has prepared a table of correction factors for measurements.

This book should be read by all petrographers making modal analyses. It will be also of much value to scientists interested in statistical methods in geological studies.

Notes and Personalia

Notes

SUMMER COURSE ON AIR POLLUTION AT MASSACHUSETTS INSTITUTE OF TECHNOLOGY—Massachusetts Institute of Technology has announced a special summer course dealing with the causes, control, and effects of air pollution to be held in Cambridge, August 11–22, 1958. Details may be secured by writing to James M. Austin, Director of the Summer Session, Room 7–101, Massachusetts Institute of Technology, Cambridge 39, Massachusetts.

NEW COURSE ON THE STUDY OF AIR POLLUTION AT THE UNIVERSITY OF NORTH CAROLINA—The School of Public Health at the University of North Carolina has announced a graduate course on Air Pollution in connection with the work in the Department of Sanitary Engineering. This will be given under a grant from the Community Air Pollution Program of the U. S. Public Health Service by Lyman A Ripperton, recently of the Los Angeles Air Pollution Control District, and Emil T. Chanlett.

NINTH ALASKAN SCIENCE CONFERENCE—The Ninth Alaskan Science Conference will be held at the University of Alaska, September 2–5, 1958. This will cover a broad spectrum of science and that portion relating to geophysics is under the Chairmanship of Christian T. Elvey, Geophysical Institute, University of Alaska, College, Alaska.

SCIENTISTS AND ENGINEERS IN RESEARCH AND DEVELOPMENT—A recent release of the National Science Foundation (NSF-58-9) notes that 230,000 scientists and engineers, military and civilian, were engaged in a wide range of organizations in the natural sciences, including engineering, in 1954. These researchers involved an expenditure of approximately $5.4 billion. The analysis indicates that about 30 per cent were engaged in physical sciences, 60 per cent in engineering, and 10 per cent in life sciences. The analysis shows that about 166,500 were working for industry-oriented organizations, 35,300 in Federal Government work, 25,200 in colleges and universities, and 2000 in other institutions.

SALARY STATUS OF FEDERAL SCIENTISTS—The U. S. Civil Service Commission, recognizing the importance of the role of scientists in the work of the Federal Government, has advanced the salary status of certain scientists to the top of the grade for the appropriate positions. This covered certain phases of geophysical science but not others, and in the case of meteorology, those who are categorized in some branch of physics received the increase but those who are characterized as meteorologists did not.

CURTAILMENT OF PLANS FOR THE *ATLANTIS*—The Woods Hole Oceanographic Institution announces that because of engine trouble the eight-month cruise of the research vessel *Atlantis* has had to be curtailed severely and the vessel has been laid up in New York for repairs. The *Atlantis* was scheduled to make observations on the physical and chemical characteristics of the Brazil Current along a line from Buenos Aires to Capetown, taking sediment cores from the ocean bottom. From Capetown the ship was to proceed to the Indian Ocean for work with the *Vema* of Lamont Geological Observatory there. It is now the plan that, upon completion of the repairs, the *Atlantis* will proceed by the most direct route to the Indian Ocean.

The contemplated work in the South Atlantic has been temporarily postponed and will probably be made by the research vessel *Crawford*.

COOPERATION BETWEEN THE WEATHER BUREAU AND THE FEDERAL CIVIL DEFENSE ADMINISTRATION ON MEASURING FALLOUT RADIATION—Plans have been announced of the establishment of nationwide facilities to measure fallout radiation at 260 Weather Bureau observatories located throughout the nation. This is especially designed to be useful in the event of a thermonuclear attack. This will bring the total number or monitoring facilities up to about 700.

SCOT EXPEDITION OF SCRIPPS INSTITUTION OF OCEANOGRAPHY—The Scripps Tuna Oceanography Research group will join with the Inter-American Tropical Tuna Commission on an expedition to the Eastern Tropical Pacific, April 28 to July 7, 1958, using the research vessel *Spencer F. Baird*. The work will extend along the western coast of North America from San Diego to Panama.

NEW JOURNAL ON THE *PHYSICS OF FLUIDS*—The American Institute of Physics has announced the publication of a new journal entitled *The Physics of Fluids*, the first number released in January-February, 1958. Inquiries should be addressed to the Institute at 335 East 45th Street, New York 17, New York.

GRANTS OF THE NATIONAL SCIENCE FOUNDATION—During the quarter ending December 31, 1957, the National Science Foundation made 409 grants totaling $15,000,000 in support of various aspects of science. During the previous quarter, 316 grants were awarded totaling about $5.5 million.

ANTARCTIC ICE DRILLING—Deep drilling of the Antarctic Ice at the IGY Byrd Station in the Antarctica reached the 1000-ft mark on January 26. The ice cores from the drill hole are removed by compressed air especially cooled to avoid melting of the snow. By means of ice cores the annual layers supply clues to the Antarctic climate reaching back many centuries. It is estimated that the snow accumulations at this site are at only about half the rate of those on Greenland, and, as a consequence, the 1000-ft level at the Byrd Station is approximately equal to the age of ice at the 2000-ft level in Greenland.

NEW MARINE MICROBIOLOGICAL LABORATORY—The Institute of Marine Science of the University of Texas has recently established a section on marine microbiology under the direction of Carl H. Oppenheimer. The Institute is situated on Mustang Island at Port Aransas, 25 miles north of Corpus Christi.

CONFERENCE ON ELECTRONIC STANDARDS AND MEASUREMENTS—A Conference on Electronic Standards and Measurements will be held at the Boulder Laboratories, National Bureau of Standards, August 13–15, 1958. Questions concerning this should be addressed to the Secretary-Treasurer of the Conference, James F. Brockman, Boulder Laboratories, National Bureau of Standards, Boulder, Colorado.

NEW IGY STAMP—The Government of the United States plans the issuance of a special postage stamp, honoring the International Geophysical Year. This follows the lead of many other nations. The Canadian stamp was issued on March 5, 1958. The U. S. stamp is scheduled for release on May 31, 1958.

SEVENTH INTERNATIONAL INVENTORS EXHIBITION—This Exhibition will be held in Brussels, June 6–29, 1958, in relation to the World's Fair being held during the summer months in Brussels. The official correspondent for the United States is Otto A. Witt, P. O. Box 1481, Milwaukee 1, Wisconsin. Fifteen categories have been established for the Exhibition.

MESOSCALE ANALYSIS AND FORECASTING—A three-day workshop devoted to mesoscale weather phenomena was held in Washington, D. C., March 3–5, 1958, under the sponsorship of the D. C. Branch of the American Meteorological Society, under the Chairmanship of Carl Reber. The speakers from out of town included James Austin, Massachusetts Institute of Technology; A. K. Blackadar, Pennsylvania State University; C. F. Chappell, U. S. Weather Bureau, Severe Local Storms Forecasting Center; Tetsuya Fujita, University of Chicago; M. G. H. Ligda, Texas A and M College; and R. G. Miller, The Travelers Insurance Companies.

FORTIETH ANNIVERSARY OF THE POLAR FRONT THEORY—The Norwegian Geophysical Society is holding a meeting in Bergen, Norway, June 19–25, 1958, to commemorate the Fortieth Anniversary of the Polar Front Theory. This will be essentially a meeting of the meteorologists with general circulation, cloud physics, and weather forecasting as themes of various sessions. The American Meteorological Society is formally participating in the meeting.

STATUS OF MAPPING IN THE UNITED STATES—New indexes of maps showing the status of topographic mapping and the status of aerial photography in the United States are now available from the U. S. Geological Survey Mapping Information Office, Washington 25, D. C.

Personalia

LESLIE F. BAILEY of the U. S. Coast and Geodetic Survey has been given the silver medal of the Department of Commerce for meritorious service.

WERNER A. BAUM, Professor of Meteorology at Florida State University, has been designated for the position of Director of University Research. Seymour L. Hess, who devoted the first semester to study at New York University is now Head of the Department of Meteorology at Florida State University.

DETLEV W. BRONK, President of the National Academy of Sciences, Chairman of the National Science Board, and President of the Rockefeller Institute for Medical Research, has been awarded the Gold Medal of the International Benjamin Franklin Society.

JAMES E. CASKEY, JR., of the U. S. Weather Bureau, has been given the silver medal of the Department of Commerce for meritorious service.

R. CORDAY COUNTS, Meteorologist in Charge, U. S.

Weather Bureau, San Francisco, and Secretary of the Pacific Southwest Regional Committee of AGU, has been elected a member of the Council of the American Meteorological Society.

Joe R. Fulks, Meteorologist in Charge, U. S. Weather Bureau Forecast Center, Chicago, has been elected a member of the Council of the American Meteorological Society.

Paul M. Fye, until recently Associate Technical Director for Research at the Naval Ordnance Laboratory in Silver Spring, Maryland, has been appointed Director of the Woods Hole Oceanographic Institution, succeeding C. O'D. Iselin, who had served as Director from 1940 to 1950 and from 1956 to 1958.

Ross Gunn has left his position as Director of Physical Research for the U. S. Weather Burean to accept an appointment as Visiting Research Professor of Physics at American University to work under a contract which the University has with the Atomic Energy Commission on their Nuclear Fusion Power Program. He has completed more than thirty years of positions of responsible scientific and research leadership in the Naval Research Laboratory and the Weather Bureau.

Charles Sumner Heidel, Staff Engineer, Water Resources Division of the U. S. Geological Survey in Montana, has recently retired after 47 years of service with the State and more recently with the U. S. Geological Survey. He had been with the Geological Survey since 1930.

Henry G. Houghton, Professor of Meteorology and Director of the Inter-Departmental Laboratory of Earth Sciences at Massachusetts Institute of Technology, was recently given the American Meteorological Society's Award for Outstanding Services.

C. O'D. Iselin has retired as Director of the Woods Hole Oceanographic Institution but will continue to be associated with it as the first Henry Bryant Bigelow Oceanographer, a Chair recently founded by the Board of Trustees of the Institution.

C. E. Jacob, Groundwater Consultant, has moved his headquarters from Orem, Utah, to Northridge, California, a suburb of Los Angeles.

Ellis A. Johnson, Director, Operations Research Office, of Johns Hopkins University, has been awarded the Army's Distinguished Civilian Service Medal "for his distinguished ability and performance."

Ralph H. King has been appointed Associate Professor of Geology at the University of Kansas and Geologist and Technical Editor for the Kansas State Geological Survey.

Julian W. Low, Research Geologist for the California Company, has written a manual of *Geologic field methods*, a companion volume to his book on *Plane table mapping*. The publisher is Harper and Brothers of New York.

Thomas F. Malone, Director of Research for The Travelers Insurance Companies in Hartford, Connecticut, and Vice President of the Section of Meteorology of AGU, has been re-elected Secretary of the American Meteorological Society.

John F. Mann, Jr., formerly Associate Professor of Geology at the University of Southern California, has organized a group of consultants on groundwater problems with headquarters at La Habra, California. The group is operating under the name of John F. Mann, Jr., and Associates, Consulting Groundwater Geologists.

Aden B. Meinel has been appointed Director of the new National Astronomical Observatory, which is under the direction of the Association of Universities for Research in Astronomy, under contract with the National Science Foundation. The site selected for the new Observatory is in Arizona. Meinel has been on leave from Yerkes and McDonald Observatories since the inception of the National Astronomical Observatory project and has served as full-time Executive Secretary to the Advisory Panel of the National Science Foundation.

James H. Nelson of the U. S. Coast and Geodetic Survey has been awarded a gold medal by the Department of Commerce for his exceptional service.

Sverre Petterssen, Professor of Meteorology at the University of Chicago, has been elected President of the American Meteorological Society.

Austin C. Poling of the U. S. Coast and Geodetic Survey has been given the silver medal of the Department of Commerce for meritorious service.

Alfred C. Redfield, Senior Oceanographer Emeritus of Woods Hole Oceanographic Institution, has been presenting Sigma Xi lectures at various colleges and universities during the winter months on the subject "The Proportions of Things in the Sea."

William Shofnos of the U. S. Coast and Geodetic Survey has been given the silver medal of the Department of Commerce for meritorious service.

Harold C. Urey, Distinguished Service Professor of Chemistry at the Enrico Fermi Institute of Nuclear Studies at the University of Chicago, soon to undertake duties at the University of California, has recently been awarded an honorary doctorate by Wayne State University.

Ernest H. Volwiler, President and General Manager of Abbott Laboratories, has been designated as Chairman of the Division of Chemistry and Chemical Technology of the National Academy of Sciences–National Research Council to succeed Frederick D. Rossini on July 1, 1958.

Harry Wexler, Director of Meteorological Research for the U. S. Weather Bureau, has been awarded a gold medal by the Department of Commerce for his exceptional service.

J. Tuzo Wilson, Professor of Geophysics at the University of Toronto, and President of the International Union of Geodesy and Geophysics, has been delivering a Sigma Xi lecture at a number of colleges and universities during the winter months on the subject "Geophysics and Continental Evolution."

M. Gordon Wolman of the Water Resources Division of the U. S. Geological Survey has accepted an appointment as Chairman of the Department of Geography at Johns Hopkins University and will assume his new post as Associate Professor on July 1 1958. He will continue on a part-time basis with the Geological Survey.

Henryk Arctowski, Meteorologist and Geologist, died February 20, 1958, at the age of 86. He was born in Warsaw, Poland, and studied at the University of Lwow, University of Zurich, and the Sorbonne. Dr.

Arctowski had an outstanding career in meteorological and climatological studies in Poland and came to the United States in the fall of 1939 to attend the Seventh General Assembly of the IUGG. While he was here, his country was overrun by the Germans and the Russians, and he never returned to Poland. He left behind a library of some 20,000 volumes at the library of Lwow where he was Professor and Head of the Department of Climatology. He continued his work in the United States as a Research Associate with the Smithsonian Institution, retiring about six years ago. He had been a member of the American Geophysical Union since 1943.

David Whitcher Mann, President, David W. Mann, Inc., manufacturer of custom-made precision instruments, died July 2, 1957, at the age of 69. He was born at Medford, Massachusetts, studied at Dartmouth College, 1910–1914. He began work in the Astronomical Laboratory of Harvard University in 1914 where he continued until 1919. From 1919 until 1947, he worked at the Jefferson Physical Laboratory at Harvard. At that time he established his own plant as a designer of custom-made precision instruments. He had been a member of AGU since 1934.

Edmund Schulman, Associate Professor of Dendrochronology at the University of Arizona and also with the University's Tree-Ring Laboratory, died January 8, 1958, at the age of 49. He was born in Brooklyn, New York, and took his bachelor's degree at the University of Arizona in 1933 and his master's degree from the same institution in 1935. He received a second master's degree from Harvard in 1938, and a doctorate in 1944. He worked at Harvard's Blue Hill Observatory in 1938, and then took up duties with the Tree-Ring Laboratory at the University of Arizona and in the Department of Dendrochronology, which he continued until the time of his death. He was a recognized world-wide authority on dendrochronology. He became a member of AGU in 1945.

Harry Oscar Wood, world-renowned seismologist, one of the founding members of the American Geophysical Union, and founder of the Seismological Laboratory of California Institute of Technology, died in Pasadena, February 4, 1958, at the age of 78. He took his baccalaureate degree from Harvard in 1902 and his master's degree from Harvard in 1904. While studying for his master's degree, he was an Assistant in Mineralogy and Petrography at Harvard. From 1904 until 1912, he did work in Mineralogy and Geology at the University of California, when he began research work in seismology at the Hawaiian Volcano Observatory where he worked until 1917. Following a period of work as Assistant Secretary of the National Research Council, he became a Research Associate in Seismology at the Carnegie Institution of Washington, on which he was engaged from 1921 until his retirement in 1942. He served as the first General Secretary of the American Geophysical Union from 1919 until 1921.

Report of the Committee of Tellers

The Committee of Tellers met in the Board Room of the AAAS Building, in which building is the office of the American Geophysical Union, at 09h on February 5, 1958 to count ballots. The following assortment of ballots was considered:

Total ballots received		1575
Rejected ballots:		
Ballots postmarked or received late or both	18	
Ballots from non-citizens of the United States	13	
Defective ballots (unmarked, or intent of voter not clear)	4	35
Qualified ballots tabulated		1540

The proposed amendments to the Statutes were adopted, reading as follows:

(1) Amend the first paragraph of Article 4 as follows:

Article 4: Sections—The American Geophysical Union shall consist of Sections as follows: (a) Geodesy; (b) Seismology; (c) Meteorology; (d) Geomagnetism and Aeronomy; (e) Oceanography; (f) Volcanology, Geochemistry, and Petrology; (g) Hydrology; (h) Tectonophysics.

(2) Amend the first paragraph of Article 5 of the Statutes to read:

Article 5: Officers of the American Geophysical Union—The officers of the American Geophysical Union shall consist of a President, a Vice President, and a General Secretary, whose terms of office shall expire June 30, 1947, but terms of office effective July 1, 1947, shall be for periods of three years, with the limitation that the President and Vice President shall not be eligible for immediate re-election; in case any office, except that of President, becomes vacant, the Executive Committee of the Union shall designate a successor in office to complete the term. In the case of the death of the President, the Vice President shall automatically become President. These officers shall be elected by mail ballot.

(3) Amend paragraph (d) of Article 3 of the Statutes as follows:

(d) *Associates*—(1) Citizens of the United States of America other than those eligible for regular membership under Article 3, Sections (a) or (b), whose interest in Geophysics is deemed by the Executive Committee of the Union to warrant their election. Associates shall enjoy the privileges of Members except that they may not be officers of the Union or of the Sections, or be delegates of the Union at International Assemblies or Meetings.

(2) Nationals of other countries having the same qualifications, elected by the Executive Committee of the American Geophysical Union; these may not vote or be officers of the Union or of its Sections, or delegates of the Union to International Assemblies or Meetings.

The tally of the ballots was as follows:

Amendment 1	Votes for	1486
	Votes against	48
Amendment 2	Votes for	1521
	Votes against	16
Amendment 3	Votes for	1500
	Votes against	30

One 1956 ballot was received voting for the officers of the union and its several sections. It was not considered a qualified ballot.

The members of the Tellers Committee, appointed by President Ewing upon nomination of the Committee Chairman, are: Bernard D. Zetler, Coast and Geodetic Survey; James N. Jordan, Coast and Geodetic Survey; B. C. Byrnes, U. S. Hydrographic Office; R. W. Seaton, U. S. Hydrographic Office; H. G. Thomasson, U. S. Geological Survey; Robert Guillou, U. S. Geological Survey; and G. E. Manger, U. S. Geological Survey.

J. H. Nelson, *Chairman*
Committee of Tellers

Nominating Committee of the Pacific Northwest Region—Norbert Leupold, Chairman of the Pacific Northwest Regional Committee, has announced the designation of Hollis N. Orem of the U. S. Geological Survey in Portland as Chairman of the Committee on Nominations for the next triennium. The other two members of the Committee are David Rockwood of the Corps of Engineers, 808 S. W. Briar Lane, Portland 1, Oregon, and Robert Beaumont of the Soil Conservation Service, 209 S.W. 5th Avenue, Ross Building, Portland 4, Oregon.

Special Announcements

Reprinting of Back *Transactions*—Volumes 1–12 of the *Transactions* (1920–1931) have been reprinted by the Johnson Reprint Corporation (excepting Volumes 3 and 5, which were mimeographed minutes only). Prices range from $4.50 to $15.00 a volume, with $80.00 as the price for the total set. Interested persons should get into touch with the Johnson Reprint Corporation, 111 Fifth Avenue, New York 3, New York.

There is also the plan to publish more recent out-of-print volumes, this depending in large measure upon the apparent market for these. Write concerning your interest to the Johnson Reprint Corporation.

Symposium on the Physics of Ice Movement—The International Association of Hydrology, IUGG, is arranging a Symposium on the Physics of Ice Movement to be held at Chamonix-Mont Blanc, France, September 16–24, 1958. Participants from the United States should forward their communications to C. C. Warnick, Engineering Experiment Station, University of Idaho, Moscow, Idaho, for consideration for inclusion in the program. Those from other countries should get into touch with their national group or with the International Secretary, Prof. L. J. Tison, rue des Ronces 61, Gentbrugge, Belgium.

Pacific Northwest Regional Meeting to be held in Portland, Oregon, November 13–14, 1958—The Pacific Northwest Regional Committee has selected Portland, Oregon, for the site of its meeting this coming autumn, November 13–14, 1958. Interested persons should get into touch with the Chairman of the Regional Committee at present, Norbert Leupold, Leupold and Stevens Instruments, Inc., P. O. Box 5082, Portland 13, Oregon, or the Secretary-Treasurer of the Region, Franklin I. Badgley, Department of Meteorology, University of Washington, Seattle 5-Washington. The new officers for the Regional Committee with terms beginning July 1, 1958 are: Chairman, Wilbur D. Simons, and Secretary-Treasurer, Vail Schermerhorn.

NATIONAL ACADEMY OF SCIENCES

Number 9 • March 1958

IGY BULLETIN

A monthly survey by the U. S. National Committee for the International Geophysical Year. Established by and part of the National Academy of Sciences, the Committee is responsible for the U. S. International Geophysical Year program in which several hundred American scientists are participating and many public and private institutions are cooperating.

First US-IGY Satellite

The first US-IGY satellite, 1958α, was launched from Cape Canaveral, Florida, at 10:48 pm EST on January 31, 1958.

Launching: The launching vehicle was a four-stage modified Jupiter-C rocket developed jointly by the US Army Ballistic Missile Agency and the Jet Propulsion Laboratory (JPL) of the California Institute of Technology. The first stage was a modified Redstone rocket with liquid propellants. The second and third stages were composed of clusters of solid propellant rockets, each forty inches long and six inches in diameter.

The upper stages of the rocket were spin-stabilized in order to minimize variations in the direction of travel owing to possible faulty alignments of rocket thrust and unbalance of the assembly. Electric motors were used to spin the upper stages at 450 rpm before take-off. After take-off the spin was increased to 700 rpm.

The over-all length of the composite vehicle is 823.3 inches. The first stage, 672.8 inches long and 70 inches in diameter, separated from the upper section at an altitude of 53 miles, when its fuel was expended, and fell into the Atlantic. The upper stages coasted to an altitude of 230 miles. At the apex of the arc, when the rocket's path was approximately horizontal, the high-speed stages were fired in sequence, increasing the orbital speed of the satellite to approximately 18,000 mph.

Satellite Characteristics: The final stage of the Jupiter-C, which carries the scientific instrumentation, is 80 inches long, six inches in diameter, and weighs 30.80 pounds after burnout (see Fig. 1). The instrument payload, carried in the forward section, weighs about 11 pounds. The protective instrument case of stainless steel weighs 7.5 pounds with an inner liner of fiber glass. The forward part of the instrument case is painted with stripes of aluminum oxide, designed to control the radiative properties of the surface and maintain the interior at a reasonable temperature. Four whip-like antennae extend from the midsection of the satellite.

Instrumentation: The satellite carries instrumentation to measure the total cosmic-ray intensity, density of meteoric matter in the satellite's orbit, and measurements of temperature both within and at the skin of the satellite.

Cosmic rays are measured by a Geiger counter. The impact of solid meteoritic particles is measured in two ways: by a microphone which picks up the actual sound of particles hitting the satellite shell, and by erosion gauges which change their electrical characteristics when broken or eroded by contact with small particles.

Thermal probes measure the temperature in the interior of the satellite and next to the outside skin.

Two radio transmitters are carried. One

radiates approximately 60 mw of power on 108.030 mc. This transmitter ceased operating during the 12th day of orbit and unexpectedly resumed transmission on February 24th. The other transmitter, radiating 10 mw of power on 108.000 mc, the primary tracking frequency, is designed to operate for approximately two months. Both transmit telemetry data on instrument readings. (A detailed description of the telemetry system was given in *Bulletin No. 8.*)

Observations: The two US radio observation nets, the prime system, Minitrack, and a supplemental system, Microlock, have tracked the satellite and have received telemetry data on every pass. The Minitrack stations utilize comparison of the phase of 108.000-mc signals arriving at different antennas to obtain the angular altitude and azimuth of the satellite. Seven Minitrack stations are stretched approximately along the 75th meridian in a "picket fence" from Blossom Point, Maryland, to Santiago, Chile. Other Minitrack stations are located at Antigua, in the Caribbean; San Diego, California; and Woomera, Australia (see *Bulletin No. 2* for a more complete description of Minitrack). The Microlock stations are at Cape Canaveral, Florida; Ibadan, Nigeria; Singapore; Earthquake Valley near San Diego, California; and Temple City, California. The stations at Ibadan and Singapore are used for telemetry only.

Although visual observations from the United States were not expected, a telescopic sighting was reported by a Moonwatch team at Alamagordo, Mew Mexico, on Saturday, February 1, and a naked-eye sighting by a Moonwatch team in Manhattan, Kansas, on Sunday, February 2.

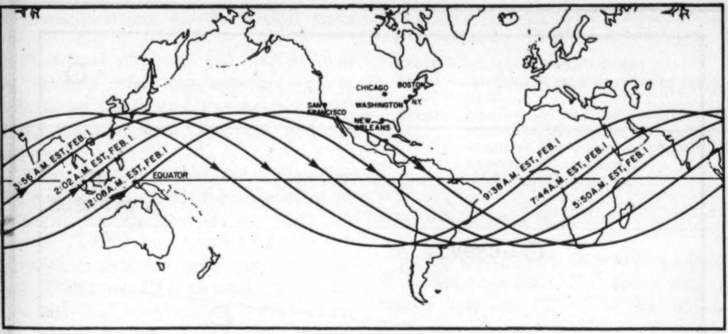

Fig. 2. *Predictions of Orbits of US Earth Satellite 1958α for the Morning of February 1, 1958. Compiled by the Naval Research Laboratory, Washington, D. C.*

The Manhattan team estimated the satellite to be as bright as a fifth-magnitude star.

Orbit: Following is the orbital information on 1958α as sent to the Special Committee for the IGY (CSAGI) of the International Council of Scientific Unions, by the USNC-IGY on February 6, 1958:

"Following orbital elements obtained by NRL from analysis 31 Minitrack observations covering first 32 revolutions 1958 Alpha. Elements include influence general perturbations and are for 0358 Zebra February one. Minimum height above earth's surface 219 statute miles maximum height 1587 statute miles period 114.95 minutes eccentricity 0.14052 inclination 33.58 degrees ascending node longitude 342.95 degrees with motion minus 4.26 degrees per day perigee argument 120.76 degrees with motion plus 6.31 degrees per day mean anomaly at epoch 14.68 degrees semimajor axis 1.2278 earth radii ascending node longitude 88 degrees 47 minutes 16 seconds East at Feb. 050647 Z, westward motion of the equatorial node is 29.13 deg. per period." (See Fig. 2.)

Phototrack

The program for volunteer photographic observations of earth satellites noted briefly in *Bulletin No. 6, December 1957*, has been formally endorsed by the USNC-IGY and is now designated program "Phototrack." Phototrack observations are expected to make a valuable supplemental contribution to the prime optical tracking network of Baker-Nunn cameras.

This program is actively supported by the Society of Photographic Scientists and Engineers (SPSE). It is designed to obtain satellite photographs meeting these specifications: Negatives are to be at least 4″ by 5″ and should be taken with a lens of at least 5″ focal length; they are to show the track of the satellite orbit against a fixed starfield background (see Fig. 3); and the trace of the satellite orbit is to contain two gaps, or displacements, timed to an accuracy of 0.1 second.

The order of accuracy of observations made to Phototrack specifications is quite high. Although the accuracy of determination of the satellite's position along its path is limited by the timing accuracy, the

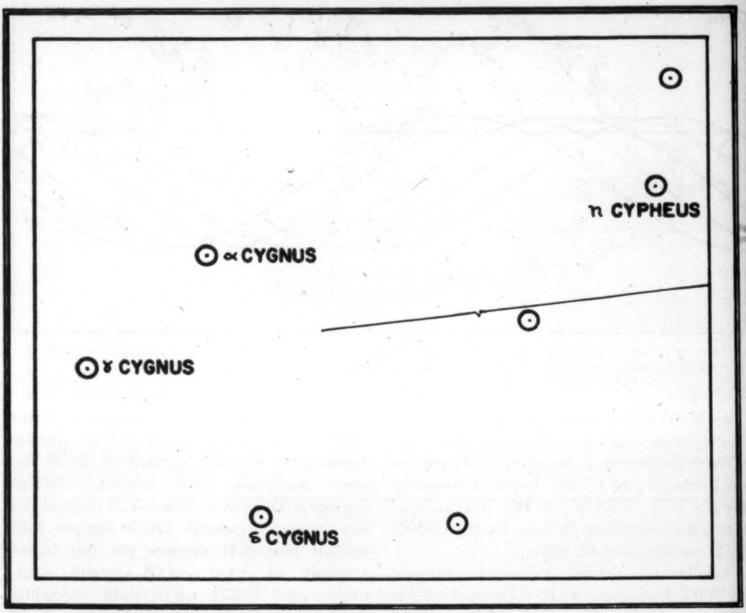

Fig. 3. *Representation of Phototrack Print Showing Track of Earth Satellite 1957β Against Fixed Starfield Background. Break in track indicates point at which camera was rapped. Taken by L. W. Tregillus, Rochester, N. Y., with a Zeiss camera having an f/6.3 Tessar lens with a focal length of 165 mm. The Kodak Royal-X emulsion was developed in DK-60 developer for 6 min at 75°F.*

position of the path itself can be determined to within 50 yards. Discrepancies of this magnitude in the satellite's predicted path can disclose information on the relative positions of the continents and on the size and shape of the earth. In addition, air drag affects the satellite's orbital period, which in turn critically affects the longitudinal changes in the satellite's apparent path over the earth. Thus, it may be possible to obtain useful air density data from measurements of the path position recorded on a Phototrack negative.

Evaluation tests are planned for improving the Phototrack technique and determining its ultimate capability.

Emulsions and Lenses

Fast emulsions must be used in Phototrack observations. Emulsions with ASA indexes of 200, developed in DK-60 for 5.5 minutes at 68°F, have recorded phototracks of 1957α1 and 1957β. These photographs were taken with lenses having apertures of less than one inch. By using the new superfast emulsions, forced development techniques, and lenses with apertures on the order of four inches, it is hoped that photographs may be obtained of objects comparable in brightness to 1957α2, which was reported to be 25 inches in diameter.

Communications for Prediction Data

Phototrack observers will need to know in advance what the optimum camera orientation will be and, in some cases, precisely when to begin, interrupt, and end exposure.

Every weekday evening since November 26, station VPZ, the Air Force station of the national headquarters of the Civil Air Patrol (CAP), has broadcast Phototrack acquisition data forecasts. These forecasts are relayed on CAP channels to the individual CAP wings and squadrons in the 48 states, District of Columbia, Hawaii, Puerto Rico, and Alaska. Should there be groups in other areas desiring to participate in the Phototrack program, efforts will be made to arrange appropriate communications through the cooperation of the IGY World Warning Agency and the cognizant IGY Participating Committee. The communications arrangements within the United States itself are presently being modified to include twilight, eclipse, and radio tracking information for satellites whose orbits are inclined at any angle to the equator. The modification will enable the CAP communications network to serve the needs of Phototrack; the visual tracking program, Moonwatch; the volunteer radio tracking program, Moonbeam; ionospheric stations; and interested newspapers within the United States.

The CAP messages will be given in the following form (The information in brackets is given only when the vertex of the track is above 40°N latitude):

On (Day) (Month) earth satellite 195- —— will be —— statute miles high and condition *(Green) (Red) (Black) (White) proceeding along curve (Inclination) (Period) [heading —— degrees across fortieth parallel] and transmitting on —— megacycles.

Vertex [fortieth parallel intercept] —— degrees west at —— Eastern Standard Time leaving condition (Black) (White) at —— degrees west at —— EST entering condition (White) (Black) at —— degrees west and —— EST.

*Black = satellite in earth's shadow.
White = satellite and satellite subpoint in sunlight.
Green = satellite in sunlight, satellite subpoint in earth's shadow (the necessary condition for visual observation of non-luminous satellites).
Red = satellite self-illuminated.

Use of Prediction Data

On any satellite pass there will be a point of nearest approach (PNA) and a time of nearest approach (TNA) to the station. Optimum camera orientation passes the camera axis through PNA, and optimum time for interruption is at TNA.

A plotting board may be prepared by placing a transparent sheet over a map or mosaic of maps showing all territory within at least 600 miles. The trace of the predicted transit can then be marked on the board with a grease pencil.

An alternative method, using a preplotted curve on a latitude-longitude grid, has been developed. Details and instructions on the use of this method are being furnished to participants in Phototrack and other volunteer observational programs.

A perpendicular line from the station position to the satellite trace will intersect the latter at the ground point beneath the PNA. The direction of the perpendicular line from the station point is the optimum azimuth for camera orientation. The length of the perpendicular line from the station to the sub-satellite point at PNA represents the distance between the station and the sub-satellite point. This is called "distance of nearest approach" (DNA). This distance can be expressed in miles or in degrees.

When the DNA and the satellite's height above the earth in kilometers or statute miles are known, camera elevation in degrees above the horizon can be determined through use of tables of elevation furnished to Phototrack observers by the SPSE or by making a trigonometric calculation.

Method of Making Exposure

The Phototrack exposure should begin as the satellite enters the camera's field, be interrupted or displaced twice as it passes along the central portion, and end as it leaves. The time of nearest approach (TNA) for a properly oriented camera would correspond to the time the satellite crossed the center of the field. When the satellite is bright enough for visual observation, the beginning, interrupting, and ending of exposure can be programmed for visual control. There may be times, however, when the satellite may be bright enough to make a Phototrack record but too faint for visual control of exposure. In such cases, the TNA must be computed in advance, and a preprogrammed beginning, interrupting, and ending carried out "by the clock."

The SPSE is furnishing all participants in the Phototrack program with detailed instructions on making, timing, and identifying the photographs. Each negative taken will be filed in a jacket with a gummed label giving pertinent information on location, exposure, and development (see Fig. 4, SPSE Form ES-1).

Society of Photographic Scientists and Engineers form ES-1

Fig. 4. *SPSE Form ES-1. These forms are designed to accompany phototrack negatives giving pertinent information on location of observation, exposure, and development.*

To establish the time of a Phototrack observation to the required accuracy, the National Bureau of Standards' time signals, broadcast by station WWV on 5, 10, 15, 20, 25, and 30 mc, may be used.

Where the observation station is remote from standard 60-cycle power, a team of observers, using a portable receiver tuned to Station WWV can come reasonably close to the desired degree of accuracy. If one observer keeps track of time by counting time ticks, the other can drop a dark slide before the lens synchronously to a time tick and hold it there for several seconds. Positive manual cut-off with the slide is preferred to use of the shutter, which is bound to introduce time-delay uncertainties.

Where 60-cycle power is available, the SPSE recommends that an auxiliary camera be set up to photograph the time on a large synchronous electric clock. If possible the clock should be mounted in the center of a blackboard so that the date, geographical position, and other observational data can be recorded on the same negative (see Fig. 5).

The clock is photographed three times on the same negative by firing an electronic flash unit. The Phototrack camera and the flash unit are wired together in such a manner that striking a metal part of the Phototrack camera or tripod with a metal striking tool completes the circuit to fire the flash. Striking the camera also displaces the traces of the satellite and the stars on the Phototrack negative.

Prior to the predicted time of the satellite passage the clock is synchronized with WWV, working lights are turned off, the flash unit energized, and the cameras opened.

center of the field of the Phototrack camera, the observer raps the grounded part of the camera or tripod with the rapping tool, then does so again. After the Phototrack exposure is completed, the timing flash is fired again, this time synchronously with the fifth tick following the double tick of WWV.

The three superimposed images of the clock face will show three different, distinguishable times. The last recorded time, being accurately keyed to the end of the fifth second by station WWV, will permit reading-out any synchronization error so that the interruption times may be given to better than the required accuracy of 1⁄10 second.

Striking the camera or tripod during exposure will produce a displacement of the satellite image, thus sharply interrupting the streak. It is unlikely that the fixed-star traces will settle down to where they left off before the tap, or that the satellite streak will continue in precisely the same line. The result will be three segments of satellite streak related to three mutually displaced sets of star traces. The shortest (middle) streak, however, can readily be related with precision to the faintest (and shortest) set of star traces. The means employed for producing the discontinuities and for recording their times are positive, do not require calibration, and supply the data in a self-evident form.

Location of Phototrack Station

By itself, a perfect Phototrack negative, together with its chronograph negative, would not constitute a significant observation. Location of the point of observation in three dimensions must also be given in such a way as to tie in with the United States Triangulation Net or to comparable surveys in other countries. This is normally done by surveying the observation station as an offset to a US Coast and Geodetic Survey triangulation station marker or its equivalent. In summary, a Phototrack station requires (1) a "closed loop" survey of its location tied into the US Triangulation Net with not more than one foot total error—though observations will still be valuable if located with errors not exceeding 100 ft.; (2) an unobstructed view of most of the sky; (3) freedom from local sources of light, particularly passing auto headlights; (4) accessibility; and (5) location near a source of 60-cycle electric power, if possible.

Appropriate topographic "Quadrangle Sheets," which may be obtained from the US Geological Survey, Washington, D. C., or found in most surveyor's offices, will show the location of nearby USC&GS triangulation station markers as small dots within triangles, and of nearby bench marks as crosses next to elevation data. About half of all bench marks are tied into the United States Triangulation Net.

The American Congress on Surveying and Mapping is encouraging its members to give assistance in surveying-in observation stations for groups genuinely interested in participating in the SPSE Phototrack program.

The Secretary-Treasurer of the Society of Photographic Scientists and Engineers, 826 Connecticut Avenue, Washington 6, D. C., will furnish detailed information on Phototrack to all persons interested in participating in the program.

Life Sciences in the IGY

While the International Geophysical Year is by definition concerned with studies in the physical sciences, the USNC-IGY has recognized that its program includes activities in relatively inaccessible regions. Therefore, research workers in the life sciences have been encouraged to take advantage of the unique opportunities provided by the IGY program and to use IGY facilities for work in their own disciplines.

Marine biology studies are conducted on all IGY oceanographic cruises (for examples of the type of work done, see the report of the "Cruise of the Brown Bear" in this issue.) Investigations in dentistry, human and animal physiology, psychology, botany, and animal migration are being conducted at US-IGY Antarctic Stations. At US-IGY Arctic Drifting Stations A and B, continuing investigations in marine biology, with particular reference to microorganisms and nutrition supply, are carried on. Even the earth satellites will be used for basic biological research. It is planned to place small living organisms, in the form of yeast, in one or more of the test spheres launched in the Vanguard program.

Brief outlines of the main problems being studied at Antarctic and Arctic IGY stations and the methods of attack on these problems are given below.

Antarctic

Dentistry: Experience on past polar expeditions indicates that dental disorders are among the most troublesome problems encountered in extreme cold. The most usual malady encountered is toothache. All devitalized and carious teeth become painful, often requiring extraction. When cold air is brought in contact with diseased teeth, the pain is often considerable. As the cold increases, alloy fillings appear to contract and pull away from the cavities they protect. Some fall out, while others leak, resulting in decay beneath the fillings. Front teeth, particularly those having large fillings and gold inlays, become quite painful on exposure to low temperatures. These difficulties have been encountered in the US-IGY Antarctic program despite attempts to prevent them by examination and treatment prior to departure from the United States.

In view of these cold-weather dental problems, the Committee on Dentistry of the National Academy of Sciences, Division of Medical Science, suggested that dental research during the IGY should be considered. The US Navy's Bureau of Medicine and Surgery has requested Navy dentists stationed at Little America and McMurdo Sound to undertake such investigations as time and facilities permit.

Among the factors being investigated are those giving rise to pain under conditions of extreme cold and their relation to dental effects. Various types of material used for fillings are tested, as well as protective devices such as rubber teeth guards worn by athletes. Temperature changes in the mouth are being measured under a variety of conditions. The relationship of dental complaints to psychosomatic factors (e.g., stress and incidence of medical complaints) is being studied.

Human Physiology: The human physiology program emphasizes the unique conditions confronting US-IGY Antarctic personnel with regard to climate, length of stay, and related factors. The degree of cold exposure is likely to be more severe than anywhere else in the world. The duration of stay is sufficiently long to uncover major trends in physiological readjustment, if such occur. The location of stations, from sea level to an altitude of about 9,200 feet, offers an opportunity to compare the effect of cold by itself with cold plus altitude on man's ability to adapt to his environment.

Work on these questions is being conducted at the Little America Station by a physiologist from the US Air Force Arctic Aeromedical Laboratory, Fairbanks, Alaska. The medical doctor at this station is assisting in the program. At each of the other US-IGY Antarctic stations the station medical doctor is carrying out basic physiological measurements.

Physiological measurements include changes in thickness of body fat, heat production, mobility of joints, and touch discrimination. Measurements are being made on personnel whose duties involve a maximum of out-of-door work, as well as others whose duties require a minimum of outside work. These measurements will be compared. Important correlative data are being obtained by various tests on physical fitness and on increase or decrease in cold injury and its relationship to these measurements.

During the 1957–58 Antarctic summer period, physiological investigations are being carried out by Nello Pace and William Siri of the University of California. This program is part of the joint British and United States Medical—Physiological Expedition and is under the auspices of the U. S. Office of Naval Research and the British Medical Research Council. Particular attention is being paid to the various traverse parties.

Psychology: It is clear from studies of situations involving stress, isolation, and deprivation that individuals respond very differently to such situations. Definitive data for the indoctrination of men going into such situations are lacking. The psychological research program has as its aim the collection of historical data of reasonably intimate personal significance by two methods: written diaries and voice recordings. These data are being collected from personnel at the IGY Amundsen-Scott South Pole, Byrd, Wilkes, and Ellsworth IGY stations.

The Program is under the direction of the

Division of Neuropsychiatry, Walter Reed Army Medical Center, and the Navy Bureau of Medicine and Surgery. Diaries have been given to personnel at these stations and they have been requested to record difficulties in adjustment to weather, limited space, and chores, as well as methods found useful for improving the situation or facilitating adjustment. Attitudes toward problems in the use of equipment and toward work progress, relations to, and importance of, radio communications with other bases and with home, and the kinds of news that seem important, are also being noted.

Development and changes in sub-group relationships, changes in informal organization of the station group, major topics of conversation, incidents of irritability and their management, complaints, distribution of activity, and attitudes toward the sense of passage of time are also being recorded by personnel, both in diary form and on records.

Subsequent analysis of these data by the Division of Neuropsychiatry, Walter Reed Army Medical Center, and the Navy Bureau of Medicine and Surgery will, it is hoped, provide a clearer picture of individual reactions and of group relations under conditions of isolation and stress.

Botany: George A. Llano, Arctic Institute of North America, is making a study of the relationship of the present vegetation of the Antarctic, specifically the lichens, to ice and snow terrain and to fluctuations in the extent of glaciation. He has made collections at McMurdo Sound, Hallet Station, and Wilkes Station.

Animal Physiology: Frozen whole specimens of Adelie and Emperor penguins are being returned from Wilkes Station for study of the anatomy of their respiratory systems.

A telemetering device is in use at Wilkes Station which, when placed inside the egg of a penguin, skua, or other bird, broadcasts the temperature to a recording mechanism. This program is under the direction of Carl Eklund, Wilkes Station Scientific Leader, and will be continued by Willis Tressler, his relief.

Animal Migration Studies: This program was initiated by Carl Eklund at Wilkes Station and will be continued throughout the coming season.

The migration and distribution of the Antarctic skua is under investigation by means of colored plastic bands attached to the legs of these birds. Personnel manning stations of other countries participating in the IGY Antarctic program have been supplied with bands of a distinctive color, so that subsequent observations will give information on the points of origin of banded birds.

Seals are being marked at Wilkes Station by means of a branding iron bearing the initials IGY. Personnel at coastal stations have been alerted to record the appearance of these seals.

Arctic

Sea Ice Studies: It is planned to study the physiology of frozen organisms, including cytological studies of organisms that survive seasonal freezing in sea ice, to determine the mechanisms which enable such organisms—diatoms, protozoans, and higher forms—to survive. In relation to this study, gas diffusion through sea ice, using the Scholander and Evans method and with emphasis upon CO_2, N_2, and O_2, will be investigated.

The solubility of nutrients in sea ice, e.g., O_2, CO_2, PO_2, NO_2, and NO_3, will be studied, as well as the activity of bacteria in sea ice, mechanical effects of freezing on organisms, and respiratory exchanges of frozen organisms.

Marine Biology: At drifting stations A and B the program in marine biology will include periodic sampling and preservation and examination of phytoplankton, zooplankton, and allied life forms.

Cruise of the Brown Bear

This report is based on material furnished by Robert G. Paquette, Department of Oceanography, University of Washington.

The study of the deep currents of the oceans is one of the primary objectives of the IGY oceanographic program. Little is known about the circulation of the deep waters, yet a knowledge of the heat exchange involved in the movement of water between low and high latitudes may be of great importance in long-range weather forecasting. Also, the rate of exchange of mineral-rich deep water with surface water determines the fertility of the oceans and sets a limit on the amount of food man can take from them.

As part of the IGY study of the deep waters, scientists aboard the oceanographic vessel *Brown Bear*, of the University of Washington, conducted investigations during July, August, and September 1957 in the Aleutian Trench, the Aleutian passes, the Bering Sea adjacent to the Aleutian Islands, and parts of the Northeast Pacific. Thirty-six oceanographic stations were occupied during the cruise.

Four of the stations were reoccupations of stations made by the non-magnetic ship *Carnegie* in 1929. In 1958, the *Brown Bear* will reoccupy seven of the *Carnegie* stations, thus making possible studies of changes in the observed phenomena in time as well as in space. Fig. 6 shows the route of the *Brown Bear* in 1957 and the stations occupied, the cruise proposed for the *Brown Bear* in 1958, and the stations occupied by the *Carnegie* on its cruise VII, 1929.

The major IGY objective of the 1957 cruise was to gather data for a north-south profile of water properties extending from the surface to or near the bottom. On most stations, chemical and temperature measurements were taken from the surface to the bottom. Eleven samples were taken from deep and surface waters for dating by the carbon-14 method. A second major objective was a preliminary survey of the circulation of water through the Aleutian

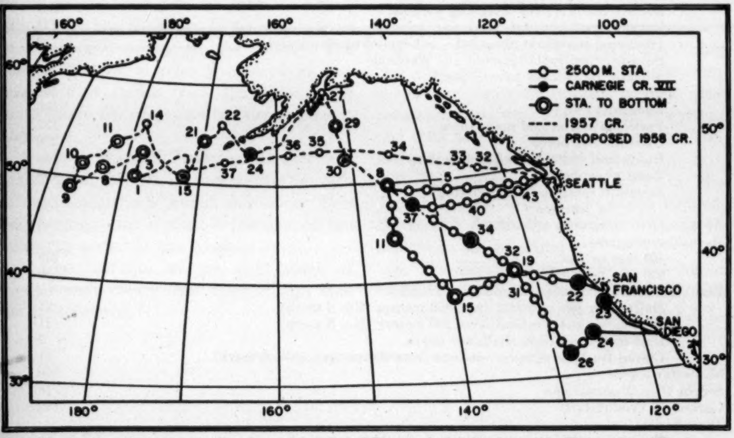

Fig. 6. *Chart Showing the Tracks of the 1957 and Proposed 1958 Cruises of the University of Washington Oceanographic Vessel* Brown Bear. *Black dots represent stations occupied by the nonmagnetic ship* Carnegie, *in 1929.*

passes as observed by a series of station sections through the passes.

Other objectives included:

1. Dating of the deep water by C^{14} methods.

2. A program of special chemistry including determination of silicate, pH, alkalinity, total phosphorus, particulate iron, manganese, calcium, and boron.

3. Routine productivity determinations by C^{14} methods, both underway and on station.

4. Direct measurement of currents north of Kodiak Island—in Shelikof Strait and on the shelf to the south. Both sets of observations were to continue for 29 hours to obtain an indication of the net current flows in these regions, which cannot be studied by the usual dynamic methods. Net flows in these areas may be important in the water-transport budget of the Gulf of Alaska.

Routine observations included salinity; temperature; oxygen; dissolved inorganic phosphate; bathythermograms and associated weather data; bathymetry; and a few bottom cores. A numerical summary of the observations made on the cruise is given in Table 1.

Although biology is not one of the primary IGY disciplines, most IGY oceanographic vessels conduct biological investigations. The *Brown Bear* made a total of 149 hauls with a 6-foot Isaacs-Kidd midwater trawl at depths ranging from about 20 to 275 meters. The hauls were made, weather permitting, along the regular cruise track. A fair number of species of rare, deep water fish were taken. A note-

worthy catch was two eel larvae still in the leptocephalus stage. At the time of capture they were alive and, except for their eyes, transparent. This may have been the first capture of this animal in the area.

Wildlife observations were made continuously and the scientific watch made an entry on a special wildlife-observations form once during each watch. These observations were supplemented by observations of the pilot house watch and by nightlight studies carried out on station when sea conditions permitted. Wildlife observed included whales, porpoises, seals, birds, surface fish, and floating organisms.

Hydrographic observations in the physical oceanographic program were analyzed and the results entered on punch cards while still at sea, thus making the data available for further analysis by machine methods soon after the ship's return to port.

Preliminary results of the program as deduced from the data at this state are:

1. The Aleutian passes are regions of high currents, where powerful upwelling and mixing processes are evident on the bathythermograms to depths as great as about 275 m. Abrupt decreases in temperature as great as 10°F appear at the surface. The modified water is readily evident at distances of 30 miles from the passes, and more subtle effects probably exist at greater distances.

2. Along Shelikof Strait, a net flow was found at all depths, setting southwest with average magnitude about 0.5 knot. This may account for a sizable fraction of the inflowing water in the Alaskan gyral.

3. The currents on the shelf south of Kodiak were rotary. Net flows, if any, were not well defined.

4. Below 2000 m the waters of the Aleutian Trench are very nearly the same throughout. One exception was noted, however: the oxygen concentration at Station 10, at the extreme westerly end of the track, is lower by about 0.015 milligram-atom per liter than at Station 15, in the central portion. Correspondingly, the temperature at the western end is higher by 0.02° to 0.10°C. Temperature increases by 0.05° to 0.20°C and oxygen decreases by 0.03 to 0.05 milligram-atom per liter along the clockwise arc from Station 15 to Station 31. Station 8 is anomalous in having the highest oxygen concentration of all stations in the Trench. Below 6000 m the temperature profiles at the several stations in the Trench are not significantly different. In contrast to the temperatures, the differences in oxygen concentration are maintained all the way to the bottom.

5. In the Trench, the oxygen concentration reaches a maximum of about 0.33 to 0.35 milligram-atom per liter at about 6000 m. It then decreases about 0.025 milligram-atom per liter towards the bottom. This latter effect may be caused by reaction of the oxygen with the metal of the bottles during the long hauling period.

6. The three deeper stations in the Bering Sea (Stations 3, 11, and 21) were very similar in temperature and oxygen concentration, and were 0.08° to 0.12°C warmer and 0.05 to 0.08 milligram-atoms per liter less concentrated than Station 15.

7. The minimum temperature in the Trench is 1.44° to 1.47°C at about 4000 m. Below this depth the gradient with depth is close to the adiabatic.

8. The salinity below 6000 m was found to be lowest at Station 15, 34.691 %, and greatest at Station 10, 34.698 to 34.706 %.

The Microbarovariograph: A New Instrument For Measuring Minute Atmospheric Pressure Variations

The following material was supplied by William L. Donn, Lamont Geological Observatory.

Studies of the interactions between the atmosphere and hydrosphere are essential to an increased understanding of the earth's heat and water budget. Such studies are, therefore, an integral part of the IGY program. (See *Bulletin No. 2, August 1957.*) In order to facilitate investigation of these interrelationships, instrumentation producing data which can be readily coupled with data obtained for related studies in the allied discipline are sought by both meteorologists and oceanographers.

Meteorologists have long felt a need for a simple, compact ultra-sensitive barograph that would respond to small changes of pressure over any given range. Such an instrument, the microbarovariograph, has been developed by the Lamont Geological Observatory of Columbia University for use in the IGY island observatory program. The instruments will be located near long-period ocean wave recorders in order to study the effects of air-to-water energy coupling.

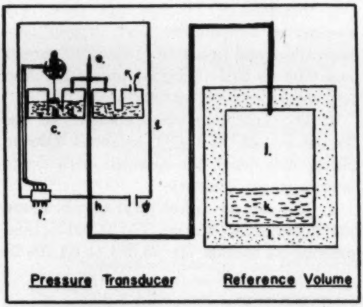

Fig. 7. *Schematic Diagram of Microbarovariograph Transducer. Legend: a. electromagnetic pickup; b. cork float; c. compliance chamber; d. Di-octal Sebacate; e. slow leak; f. metal cover; g. fast leak; h. plastic tubing; i. electrical connector; j. reference volume; k. calcium chloride solution; l. thermal insulation.*

Basically, the microbarovariograph pressure unit is designed to study: (1) propagation of internal waves in the atmosphere, and (2) the phenomena of wave coupling between the atmosphere and oceans.

The passage of internal waves along an atmospheric discontinuity aloft produces surface perturbations in pressure and wind. The wind effect is difficult to isolate if the ambient wind is strong, but the pressure variations can be recorded easily by the microbarovariograph, permitting study of the velocity and propagation direction of the waves aloft. Moreover, under the proper conditions, violent natural and artificial disturbances can be detected by an array of these instruments at a great distance from the event. Such information is of great value in understanding the dynamic structure of the atmosphere.

Strong marine or lake storm surges have occurred from the effects of coupling to corresponding surges (often waves) in the air. These severe disturbances can usually be detected by conventional instruments

but are too infrequent to provide adequate data for complete study. The sensitive microbarovariograph used in conjunction with a long-period wave recorder permits study of less pronounced but scientifically important cases of coupling. From these a better understanding of the energy transfer between sea and air can be gained.

The instrument is also excellent for the study of short-period turbulence in the air; its response shows every gust of wind. It also shows long-period pressure variations and, owing to its ability to record thermal effects, on clear days it can be used to mark the approximate times of sunrise and sunset.

A record of small amplitude, long-period pressure changes will be of particular value in the study of tsunami waves (so-called tidal waves produced by submarine earthquakes, landslides, or volcanic action) since it is expected that pressure oscillations in the atmosphere will affect the long-period wave record. In tsunami studies, the atmospheric pressure record will be applied as a correction to the water pressure record. Widespread use of the instrument in the Atlantic will also aid in gathering data for a closer study of the propagation charac-

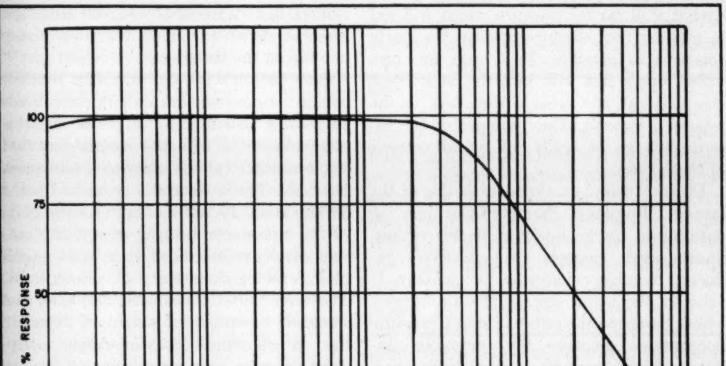

Fig. 10. *Typical Response Curve of Microbarovariograph Transducer.*

teristics of internal waves in the atmosphere.

Microbarovariographs are or will be installed in Iceland, the Azores, Bermuda, Barbados, Ascension, St. Helena, Texas Tower No. 4, and Fire Island, New York. Argentina plans to use two instruments in connection with its IGY program.

The microbarovariograph is a rate-of-change pressure recorder, utilizing a pressure transducer developed by Wallace of Wallace and Tiernan, Inc. The pressure transducer is essentially a U-tube manometer (see Fig. 7) open at one end to the dynamic pressure fluctuations of the atmosphere and at the other to a thermally insulated chamber maintaining a relatively constant temperature. The fluid used in the transducer is Di-Octal Sebacate, a commercial plasticizer, selected especially because of its small temperature coefficient of expansion and low volatility and creep. A saturated solution of calcium chloride is used to adjust the reference volume to a pre-determined value and to maintain within it a partial pressure which will aid in keeping the reference pressure as nearly constant as possible. Two leaks are provided, one a fast leak into the compliance chamber and the other a slow leak in the reference volume. The response of the instrument can be easily set by adjustment of these leaks.

Figure 8 shows an electrical analog of the system. Response characteristics can be determined by an analysis of this circuit. Short-period changes are effectively reduced by the connection of another U tube in the same line as the transducer, which dampens the effect of quick pressure fluctuations. Because the thermally-insulated reference volume is large in comparison to the pickup volume in the manometer, the temperature drift is negligible.

Figure 9 is a block diagram of the recording system. The armature of the pickup is connected to the float on the surface of the fluid in the transducer. The mechanical pressure fluctuations are converted into direct current by a simple electro-dynamic pickup. The d.c. signal produced modulates a 60-cycle alternating-current carrier. Following two stages of amplification, a demodulator converts the output signal to d.c., which drives a Lamont microfilm recorder. The feed-back circuit utilizes a magnetic modulator to return the d.c. output signal to a.c. The maximum resolution possible is about .002 mb. The approximate dynamic pressure range is 0.12 mb. The operating sensitivity used depends upon the resolution and the response desired, with the limitation that the slow leak must be capable of effectively eliminating all large diurnal pressure changes.

Figure 10 is a typical response curve of the transducer. Reference to the curve shows that it is relatively flat between 10 secs and approximately 200 secs. It reaches half value at about 2000 secs. The response curve was computed from a step impulse on the transducer.

Once set up with the microfilm recorder loaded, the instrument can operate unattended for one month. A panel meter is placed in series with the recorder so that the operation can be checked at frequent intervals. The instrument operates from a 50–60-cycle, 110-volt a.c. line. All the parts of the transducer housing except the outside cover are machined from plastic, and plastic tubing connects the various units. The three units (transducer, amplifier, and recorder) have a total weight of about 12 lbs. A standard Esterline-Angus strip-chart recorder may be substituted for the Lamont microfilm recorder by using alternate output plugs on the amplifier.

IGY BULLETIN

A monthly survey by the U. S. National Committee for the International Geophysical Year. Established by and part of the National Academy of Sciences, the Committee is responsible for the U. S. International Geophysical Year program in which several hundred American scientists are participating and many public and private institutions are cooperating.

IGY Antarctic Oversnow Traverses

Although 11 nations have established 38 new scientific stations in the Antarctic for the IGY, observations made at these widely-distributed stations can furnish only a portion of the geophysical data needed for a complete understanding of this 6,000,000-square-mile region of ice and rock. To fill some of the major gaps, a series of oversnow scientific traverses were organized as part of the US-IGY Antarctic Program for the summer seasons of 1957–58 and 1958–59.

Three major oversnow traverses scheduled for the 1957–58 summer season by the US-IGY have been completed—the Ross Ice Shelf traverse from IGY Little America Station; a traverse of parts of Marie Byrd Land and the Ellsworth Highland from IGY Byrd Station; and a traverse across the Filchner Ice Shelf and parts of Edith Ronne Land from IGY Ellsworth Station (see Fig. 1). They were preceded in January and February 1957 by a tractor-train traverse from Little America to Byrd Station, 647 mi eastward over the ice cap. Glaciologic and seismologic measurements were made on this first traverse; experimental and logistic procedures and techniques were tested and perfected. A full four months of field work is planned for each of the summer seasons, which begin in October and end in March, despite an interruption about mid-season for the annual replacement of personnel.

Scientific Objectives

In the traverse program seismic techniques are used to measure the thickness of the ice and to determine the character of the subglacial floor and of exposed land areas. Ground control, for subsequent survey operations, is established wherever rock outcrops occur. Core, pit, and surface studies are made to provide data on snow stratigraphy and on the movement, volume, thermal and hydrologic regimen, recent mass changes, and crystallography of the ice.

Gravity measurements, partly in association with the seismic work, and measurements of the earth's magnetic field strength and of magnetic compass variations are included in the basic traverse programs. Standard meteorological information is obtained on all traverses for transmittal to the IGY Antarctic Weather Central at Little America Station. (*Bulletin No. 4, October 1957*, contains a detailed report on the Weather Central.) Airborne seismic and glaciological traverses, to make spot measurements in areas inaccessible to surface parties, are also part of the program.

Although geologic study reveals that the Antarctic ice mantle was once about 1000 ft thicker than it is now, it is not yet known whether the total ice mass is at present increasing or decreasing. Some estimates suggest that it may be in a state of approximate equilibrium, but a large

body of detailed glaciological and micrometeorological information from both the fixed stations and a broad network of oversnow and airborne traverses must be accumulated and analyzed before final conclusions can be reached.

The early traverse from IGY Little America Station to Byrd Station resulted in the first extensive evidence that the Antarctic continent is overlaid with a far greater volume of ice than long thought. (Byrd Station, about 5000 ft above sea level, rests on about 10,000 ft of ice.)

Gravity and seismologic data obtained on these traverses may show whether the sub-sea-level portion of the ice sheet, such as exists beneath Byrd Station, occurs in fjord-like depressions similar to those found to exist under the Greenland ice cap and Queen Maud Land or indicates the presence of a great frozen sea in West Antarctica.

Data acquired on the traverses will also contribute to knowledge of the relationships between Antarctic ice and the supply and movement of cold ocean waters, as well as between the ice and Southern Hemisphere weather and climate.

1957–58 Traverses

IGY Little America Station—The traverse party from Little America had as its objective during the past season the study of the mass and volume, thickness, hydrologic economy, morphology, and structure of the Ross Ice Shelf. The depth to the sea bottom beneath the floating ice shelf was measured by seismic methods, investigations were made of mountain ranges and peaks along the edge of the shelf, and wind-drift—or sastrugi—patterns were studied.

The Ross Ice Shelf extends more than 400 mi into the Ross Sea embayment from a point about 300 mi from the South Pole. Its maximum width is approximately 500 mi and its area about 160,000 square mi. Recent seismic studies by IGY scientists at Little America Station made in the vicinity of the station but away from the edge of the shelf, show an ice thickness ranging from nearly 790 to about 1050 ft. The ocean bottom was shown to be about 2070 to 2155 ft below the ice surface, indicating that this part of the shelf floats on well over 1000 ft of water.

Gravity measurements made this summer at IGY Little America Station indicate vertical movement of the shelf of several feet. Motion is very small 7 mi from the station and entirely absent at distances of 20 to 30 mi. It has been estimated that the shelf moves seaward at the rate of about 5 ft/day. The additional seismic and gravity measurements accumulated on the Ross Ice Shelf traverse will ultimately permit a more complete synthesis of the physical character of the entire shelf.

It is apparent from ice-fracture patterns that the Ice Shelf is grounded in many places. Although the islands on which it is grounded do not generally penetrate the ice, they may be identified by hinge cracks, higher elevations, and ice-fracture patterns. These features were mapped wherever possible along the traverse route.

Initial plans for the Ross Ice Shelf traverse prescribed a triangular route from Little America Station westward to McMurdo Sound, southeast to the Beardmore and Liv Glaciers at the southern edge of the shelf, and northeastward back to Little America Station (see Fig. 1). This route was generally adhered to, although McMurdo Sound was by-passed to maintain the planned time schedule, and several deviations were made for special studies.

The traverse party, consisting of eight men led by Albert P. Crary, Station Scientific Leader at Little America and Deputy Chief Scientist for the USNC-IGY Antarctic Program, left its home station on October 24, 1957.

Reports issued while the traverse was in progress listed, through January 1958, a total of 34 seismic, 179 gravity, and 160 magnetic stations occupied; 26 glaciological pit studies made; 130 ramsonde measurements taken (the ramsonde, or ram penetrometer, is an instrument for determining physical properties of the snow by recording the amount of force required to drive a rod a given distance into it); and weather observations made at 281 stations. In addition, ice temperature and density were measured at a depth of about 30 ft in 31 drill holes, 55 ft in one drill hole, and 65 ft in three drill holes.

R. L. Viets, geomagnetician at Little America Station, visited the traverse party briefly at 82°S, 170°E, where he was able to make successful magnetic field observations with a magnetometer provided by New Zealand IGY scientists.

Elevation of the ice surface was measured continuously along the traverse route by the "altimetry leap-frog method," which employs three crews to make successive atmospheric pressure measurements at each site. Sites occupied are five miles apart. This method provides enough data for each position to permit corrections for fluctuations in atmospheric pressure, allowing much more accurate altitude determinations than would be possible with single observations.

Employing this technique, the Ross Ice Shelf traverse party found that the shelf's elevation varies overall by about 60 ft. In general, however, the Ice Shelf appeared virtually featureless. Only two small islands, situated just west of Roosevelt Island, and two small depressions broke the evenness of the ice surface during the first leg of the route.

The traverse party returned to IGY

Table 1. *Seismic Data Obtained on Byrd Traverse 1957—58*

Lat. (S)	Long. (W)	Elev. above sea level (ft)	Ice Thickness (ft)	Remarks

Little America Station on February 13, 1958, after 113 days in the field. The overall length of the traverse was 1450 mi.

IGY Byrd Station—The broad objective of the Byrd Station traverse for the 1957–58 summer season was to determine the general nature of the ice sheet and of protruding mountains in eastern Marie Byrd Land and in the Ellsworth Highland to the east of Byrd Station. Although specific types of measurements were similar to those made on the Ross Ice Shelf traverse, the existence of thousands of feet of inland ice resting on a bedrock surface in the region covered by the Byrd party constituted a major environmental difference.

The Byrd Station traverse party, led by Vernon Anderson, IGY glaciologist, departed on November 19, 1957. Radio schedules were arranged with the Ellsworth traverse group for exchange of information.

Excellent seismic reflection data were obtained throughout the traverse. Table 1 gives ice thicknesses and elevations of the surface at representative points along the first and second legs of the traverse; at only one of these locations does the subglacial floor rise above sea level, and at the last location the ice thickness, surface elevation, and bedrock depth are similar to those at Byrd Station. At distances of 100–200 mi west of the Sentinel Mountains, the apex of the second and third legs of the traverse, ice thicknesses were generally more than 10,000 ft; the maximum measured was 11,610 ft. The seismic records for most of the traverse route indicate rugged, variable topography characterizing a subglacial floor almost everywhere below sea level.

The Byrd Station traverse party collected samples of volcanic rocks and lichens in the region of an unnamed mountain range about 250 mi northeast of Byrd Station. One unusual biological observation was the discovery of penguin tracks along the traverse route at a point more than 150 mi from the nearest known coast.

Although figures for the entire traverse are not yet available, an idea of the party's experimental activities may be formed from the following list compiled for the month of December, 1957. During that period, the traverse party made 13 short refraction profiles, 110 gravity and magnetic readings, 12 glaciological pit studies, and 55 intermediate-depth ramsonde measurements. Six days were spent at the Sentinel Mountains making long seismic-refraction profile studies and collecting rock samples. After leaving the Sentinels, increasing surface noise interfered with seismic work.

At the Sentinels, study of a nunatak (isolated peak or hill projecting through a glacial surface) indicated a former ice level 800 ft above the present surface. Investigations were made and rock samples collected at five nunataks. Glaciological studies along the traverse route showed an accumulation of about 20–30 inches of snow during the past year.

The traverse ended on February 23, 1958, with the return of the party to IGY Byrd Station after 96 days in the field and a trek of about 1200 mi.

IGY Ellsworth Station—The Ellsworth Station traverse investigated the Filchner Ice Shelf and the inland ice of Edith Ronne Land, combining the types of measurements made by both the Little America and Byrd traverses. An important goal of this traverse was to occupy a point that could also be reached by next summer season's Byrd Station traverse, thus providing a link for the correlation of data.

The traverse party left IGY Ellsworth Station on October 28, 1957, led by Edward C. Thiel, glaciologist. The party had been held up several days while airborne efforts were made to find a safe passage through a heavily crevassed area in the first 50 miles south of Ellsworth Station. A crevasse-free passage towards the east and with elevations of 700 to 3000 ft above sea level was found.

The party deviated about 120 mi from the planned route to make geological studies and collect rock specimens at a newly reported mountain range. The range, estimated to be 11,000 ft high in places, is reported to be about 400 mi from the South Pole, trending east-west throughout its length of about 100 mi. It was discovered from the air by Finn Ronne, then scientific leader at IGY Ellsworth Station.

On December 22, another mountain range, first sighted on a reconnaissance flight early in 1957, was reached. These mountains have an average height of 6500 ft and extend east-west along 82°33′S for about 30 mi, between 51° and 55°W. Black bands were noted high on the mountains, and a 5000-ft escarpment was discovered on the southern side.

A 3200-ft, ice-covered island extending for about 230 mi south and west from Gould Bay was observed for the first time. Seismic soundings showed the land surface beneath the island's ice mantle to be hundreds of feet above sea level. Other islands, whose contours were not fully delineated, were seen still farther westward. They appear to tie in with land in the Sweeney and Lowell Thomas Mountains at the western end of the Filchner Ice Shelf.

The traverse party encountered several crevasse fields along the route. In early January 1958, after reaching a difficult crevasse field at 78°40′S, 69°W, about 80 mi from Mt. Hassage, at the apex of the second and third legs of the traverse, the party was evacuated by air. A relief party had been flown in to attempt to continue the traverse. To that point, the traverse had covered 816 mi, including a large portion of the Filchner Ice Shelf and considerable inland stretches. The relief party backtracked in an effort to find an open route to Ellsworth Station. It then turned southward to the midpoint station, where the vehicles and equipment were cached for use by next year's party.

Other traverses: 1957–58—Personnel remaining at US-IGY Antarctic stations conducted several short traverses in the vicinities of their stations during the 1957–58 Antarctic summer season. The aims were basically similar to those of the major traverses.

The airborne seismologic traverse program was inaugurated with flights into Victoria Land, on the ice cap east of McMurdo Sound. Original plans scheduled landings at 50-mile intervals. Between January 2 and 22, 1958, three stations were occupied for the purpose of making glaciological, gravity, and seismological observations. Station A was occupied at 77°33′S, 158°30′E, at an elevation of 7750 ft, Station B at 77°09′S, 155°05′E and an elevation of 8300 ft, and Station C at 77°22′S, 139°48′E, elevation 8850 ft. Results obtained at these and other stations occupied in this program will be compared and correlated with those obtained on the oversnow traverses.

A combined New Zealand-United Kingdom Trans-Antarctic Expedition, using the US-IGY South Pole Station as a linkage point, was conducted during the past Antarctic summer, completing the first continental crossing of the Antarctic.

The New Zealand group, under the direction of Sir Edmund Hillary, left Scott Station (N. Z.), at the northwest corner of the Ross Ice Shelf, on October 14, 1957. Its purpose was to establish supply dumps for the United Kingdom party. It reached the Pole, about 1200 mi distant, on January 4, 1958. The United Kingdom party, led by Vivian E. Fuchs, left Shackleton Station, on the Weddell Sea, on November 24, 1957; it arrived at the South Pole on January 19, 1958. This was the first time the regions between the Weddell Sea and the South Pole, a distance of more than 2000 mi, had been crossed overland.

The party left IGY South Pole Station on January 24, and reached Scott Station, the terminus of the traverse, on March 1, 1958. Seismic studies made by the Fuchs party should provide the first profile of the ice thickness, surface elevations, and subglacial surface across Antarctica from the Weddell Sea to the Ross Sea.

During the 1957–58 summer season, USSR-IGY oversnow trail parties conducted traverses into the interior of Antarctica from IGY Mirny Station, on the Queen Mary Coast in East Antarctica; their goal was to establish scientific stations at the south geomagnetic pole and the "pole of inaccessibility." One party reached 78°27′S, 106°52′E, a few miles from the geomagnetic pole, on December 16, 1957. The USSR-IGY Vostok II Station was established at this location, 10,500 ft above sea level. This party reported winds up to 134 mph at a point along the traverse route 200 mi west of Mirny. Another party reached 78°24′S, 87°35′E, about 425 mi from the pole of inaccessibility, on February 12, 1958, where it established the USSR-IGY Sovietskaya Station. This station, deep in the interior of Antarctica, is at an elevation of about 12,100 ft.

Planned US-IGY Traverses

Personnel of IGY Little America, Byrd, and Ellsworth Stations will conduct further oversnow traverses during the 1958–59 Antarctic summer. The Little America group plans a roughly diamond-shaped traverse route on the Rockefeller Plateau north and west of Byrd Station, from 80°S, 140°W to 77°S, 130°W; from there to 80°S, 125°W in the vicinity of Byrd Station; then back to the starting point.

The Byrd Station party will cover a route in the southern part of the Ellsworth Highland, from the station to about 81°S, 75°W, to occupy a point first occupied by the 1957–58 Ellsworth Station traverse. It will then proceed to Horlick Mountain, at 85°S, 90°W, and back to Byrd Station. The total distance to be covered on the Byrd Station traverse is 1065 mi.

The route originally proposed for the 1958–59 Ellsworth traverse is heavily crevassed. As a result, alternative routes are under consideration.

Organization and Logistics

Each major US-IGY traverse party was staffed with two glaciologists (except the Ross Ice Shelf party which had three), two seismologists, one gravity observer, and support personnel. In each party were personnel capable of driving and maintaining the vehicles, navigating, operating and maintaining radios, cooking, administering first aid, and maintaining a field camp. Additional scientific personnel were added occasionally for special studies.

Indispensable airborne and other logistic support for the traverses was supplied by U. S. Navy Task Force 43 under the command of Rear Admiral George Dufek.

The vehicles used were Tucker Model 743 Sno-Cat Freighters, US Army M29C Weasels, and cargo sleds. Each Sno-Cat is capable of hauling 2300 lbs of cargo and passengers and of towing up to 2½ tons at cruising speeds of 10–15 mph. The four-passenger Weasels can tow sled loads of as much as two tons. The Sno-Cats and Weasels are equipped with heated cabs for both living and working quarters. During the 1957–58 traverses, each party used three Sno-Cats towing cargo sleds.

Lead vehicles of all traverse parties were fitted with electronic crevasse detectors to assist in finding safe routes. Gyrocompasses, which permit navigation independently of the earth's magnetism, were used instead of magnetic compasses, generally very unreliable in polar regions. Each oversnow traverse party carried one high-frequency radio transmitter having a range of .35 to 9.05 mc and capable of 125-watt CW (continuous wave) or 40-watt voice transmission. At least one medium-to-high frequency receiver was also carried by each party, as well as a portable 100-watt unit capable of 2- to 18-mc CW or voice transmission and reception.

Ski-equipped aircraft were used in advance of the traverse parties to help them choose the easiest and safest routes, providing reports and aerial photographs of the terrain to be crossed.

Experience has shown that such oversnow traverse parties can operate for distances of about 300 mi on the fuel they can carry. Hence, the total range of operation, 1200 mi or more for the major traverses, depended on airborne fuel depots established at the required intervals and on airdrop support when needed. In other respects, each traverse unit was as self sufficient as possible, carrying with it spare radio equipment and emergency gear to be used in case a vehicle was lost or damaged.

Physical obstacles, such as crevasse fields, and scientific considerations dictated some departures from original traverse routes.

World Warning Agency Decisions

October 3, 1957–January 1, 1958

During the first three months of the IGY, 14 periods of Alerts and 4 SWI (Special World Intervals) were declared by AGIWARN, the IGY World Warning Agency, operated by the National Bureau of Standards at Fort Belvoir, Virginia, near Washington, D. C. (See *Bulletin No. 5, November 1957*, for details of this first three-month IGY period.)

During the next three-month period, solar activity was in general lower; only six periods of Alert, totalling 23 days, and two SWI, totalling four days, were declared. One of the SWI was unsuccessful in that no major solar disturbance with associated terrestrial effects followed. During the other SWI a short but relatively severe geomagnetic disturbance took place.

In the second three months, sunspot activity, as measured in terms of the provisional Zurich monthly sunspot number, continued high, and the smoothed sunspot number continued to rise.

Following are the Alerts, SWI, geomagnetic disturbances, and major flares that occurred from October 3, 1957, to January 1, 1958. Alerts and SWI are numbered according to a simple chronological system in use by AGIWARN. The numbers in this list continue serially from the last Alert, number 10, which started on September 27, and the last SWI, number 6, which started on September 12, 1957. (The list of Alerts and SWI which appeared in *Bulletin 5*, p. 14, may be modified to reflect this numbering system.)

Oct. 9 034x Class 3 flare
Oct. 14 1600 Alert #11 starts
Oct. 16 0152 Class 3 flare; sudden ionosphere drop-out and gradual recovery
Oct. 16 0416 Class 3 flare
Oct. 19 064x Class 3 flare
0700 Class 3 flare

Oct. 20 1600 Alert #11 finishes
1637 Class 3+ flare
1644 Class 3+ flare
1700 Class 3 flare; sudden ionosphere drop-out and gradual recovery
Oct. 21 1600 Alert #12 starts
Oct. 22 0001 SWI #6 starts
Oct. 23 062x Class 3 flare; sudden ionosphere drop-out and gradual recovery
1600 Alert #12 finishes
2359 SWI #6 finishes
Nov. 12 1600 Alert #13 starts
Nov. 15 1600 Alert #13 finishes
Nov. 24 0848 Class 3+ flare
1600 Alert #14 starts

As an illustration of how AGIWARN uses information and advice from other centers, an excerpt from a report by R. C. Moore, Director of AGIWARN, is given below. The code groups have the following meaning:

ALNIL—No Alert
ALBEG—Alert begins
ALCON—Alert continues
ALFIN—Alert finishes
INBEG—SWI begins
INCON—SWI continues
INFIN—SWI finishes

"For several days prior to November 22 the sun was relatively quiet. Without exception the nine centers (Anchorage, Boulder, Darmstadt, Kokubunji, Moscow, Nederhorstdenberg (NERA), Paris, Prague and Sydney) advised that no Alert be started (ALNIL); the AGIWARN decision on each of these days was ALNIL.

November 22: Eight centers suggested ALNIL, while Sydney wanted to begin an Alert (ALBEG). A solar region then well west of central meridian produced several flares, but none of great interest. The AGIWARN decision was ALNIL.

November 23: Seven centers advised ALNIL; Moscow's advice was ALBEG; no message was received from Paris. The western region's activity level appeared to be rising, but the situation did not seem to warrant the starting of an Alert, so the AGIWARN decision was ALNIL.

November 24: Boulder, Moscow and NERA advised ALBEG; Anchorage, Darmstadt and Prague advised ALNIL. Kokubunji and Sydney suggested ALBEG also but the messages arrived too late, and no message was received from Paris.

By now the western region was no longer active, but an eastern area which had appeared at the east limb of the sun November 20 and had exhibited only minor activity during the first four days of its transit suddenly became interesting. It produced a series of flares ranging in importance from 2 to 3 plus. This flare activity was accompanied by well observed major radio noise events.

Based on the above activity, plus encouragement from three of the six centers, AGIWARN began an Alert.

November 25: Five centers advised that the Alert be continued (ALCON) and four centers (Darmstadt, NERA, Paris and Sydney) suggested that a Special World Interval be started (INBEG).

Although only one of the four centers (NERA) which suggested INBEG had advised ALBEG the preceding day, the timing of the events which had precipitated the November 24 ALBEG seemed to warrant the starting of an Interval. The AGIWARN decision, therefore, was INBEG.

November 26: The Interval began at 0001 UT and a sudden commencement of geomagnetic disturbance started at 1455 UT. Eight centers advised that the Interval be continued (INCON) and one (Paris) suggested it be finished (INFIN) but the Alert continued (ALCON). The AGIWARN decision was INCON.

November 27: Five centers advised that the Interval be stopped but suggested that the Alert be allowed to continue. Four centers (Darmstadt, Moscow, Prague and Sydney) thought that the Interval should continue.

The region associated with the disturbance had produced no major flare activity since November 24. In addition, the storm appeared to be subsiding quickly. The AGIWARN decision, therefore, was ALFIN INFIN.

November 28: The disturbance was officially ended about 1200 UT November 27. All centers advised ALNIL and the sun continued to be quiet. The AGIWARN decision was ALNIL."

Cosmic-Ray Balloon Experiments

Soft Radiation Associated with Auroras and Geomagnetic Activity

As long ago as the summer of 1953, L. H. Meredith, M. B. Gottlieb, and J. A. Van Allen detected the presence of new "soft" (low energy) radiation at altitudes above 50 km by means of Geiger counters in a series of rockoon (balloon-launched rocket) experiments. During the summers of 1953, 1954, and 1955, Van Allen's group observed the latitude distribution and temporal variation of the effect; these strongly suggested that it was auroral-associated, even though all flights were made in the daytime, and no direct correlation with visual auroras could be shown.

Using additional experimental data taken with a scintillation detector, Van Allen concluded that the soft radiation was probably X-rays in the 10–100 kev (1–0.1Å) range rather than protons or electrons. This was supported by laboratory experiments and energy calculations which suggested that the X-rays might be produced as "bremsstrahlung" from incoming electrons penetrating to 90–110 km in the atmosphere. (When a particle having kinetic energy in the X-ray range suffers a collision with an atom, and this energy is released in the radiant form, it is termed "bremsstrahlung," literally "the deceleration or braking radiation.") The soft radiation detected would therefore have been created in the atmosphere rather than incident upon it from outside, as in the case of low-energy cosmic rays themselves.

In the course of the first few months of the IGY, two series of cosmic-ray balloon flights have demonstrated that soft radiation is sometimes present at much lower altitudes in the atmosphere. One series of 20 flights launched at Minneapolis during July, August, and September 1957 was conducted by E. P. Ney and J. R. Winckler of the University of Minnesota to provide week-by-week checks of cosmic-ray intensity and also to coordinate with other IGY cosmic-ray balloon programs in the field. Among the latter was a series of flights at Fort Churchill under the direction of Kinsey Anderson of the State University of Iowa. The following is a brief summary of some of the more significant observations of soft radiation and associated events made on these flights. Recent IGY rockoon observations of auroral soft radiation, made by Van Allen, were reported in *Bulletin No. 5, November 1957*.

The high level of solar activity during the beginning of the IGY produced a number of auroral displays of great intensity. During three of them, on July 1, September 12, and September 21–22, 1957, the Minnesota workers were successful in placing a balloon at high altitude during the aurora and observing soft radiation at levels corresponding to pressures from 8 gm/cm^2 to 40 gm/cm^2. (In an isothermal atmosphere at 273°K, or 0°C, these pressures would correspond to altitudes of 38.9 km and 26.1 km, respectively. At higher or lower absolute temperatures, the corresponding altitudes are proportionally greater or lower than those cited.) Instruments flown on these occasions were an ionization chamber, a single Geiger counter, and, on September 22, a special photon counter.

J. R. Winckler and L. Peterson of Minnesota have reported that during the flight of July 1 an aurora began at 0330Z while the balloon was floating at the 8 gm/cm^2 level. A large initial ionization burst of ten minutes' duration occurred, followed by a weaker one lasting fifteen minutes and another, still weaker, peaked at 0420Z. Fluctuations were seen until 0630Z in both the ionization chamber and Geiger counter. The large initial effect was associated with auroral rays near the zenith, and the increases in rates were roughly correlated with visual observations of increased brilliance near the zenith.

It should be emphasized that this was the first recorded instance of a directly observ-

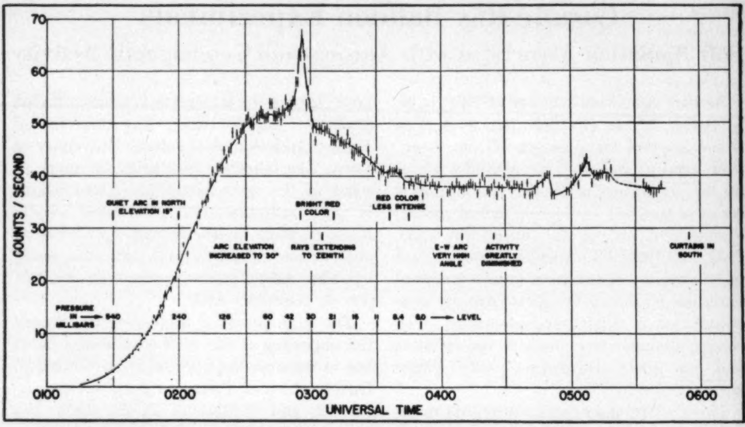

Fig. 2. Geiger counter record taken on a balloon flight at Minneapolis during the auroral display of September 12, 1957. One millibar of pressure is equivalent to 1.08 gm/cm².

able correlation of visual aurora and soft radiation, although, as noted above, the distribution and variation of the kind of radiation observed by Van Allen some years earlier implied a close connection with visual auroras.

In Figure 2, the graph of Geiger counter data obtained on September 12 shows a clear correlation with visual auroral phenomena. A smooth steep rise, middle altitude maximum, and decline to a steady counting rate is typical of a quiet-day record as the balloon rises to altitude. On this day, however, a large increase occurred at the relatively low level of 40 gm/cm²; other deviations from quiet-day behavior are shown by the fluctuations of the line drawn through the observational points. A peak X-ray intensity above the atmosphere of 500 milliroentgens/hour was estimated from data obtained on this flight.

In the July 1 experiment, both the integrating ionization chamber and single counter recorded strong bursts with large fluctuations. The ratio of the two rates—the relative mean ionization per count—varied from 0.2 to 0.26 prior to the commencement of the auroral effect, but during this effect the ratio of the excess rates was 1.3 to 1.4. The value of 0.2 is characteristic of fast, singly-charged particles in the lower atmosphere, while the increase to 0.26 at higher altitude was attributed to increased flux of heavy primary nuclei at those levels. Laboratory studies of the ratio of ionization per count for X-rays of various energies and for gamma-rays showed that the experimental observation of a ratio of 1.4 under 8 gm/cm² of atmosphere is consistent with X-rays in the energy range 50–70 kev. These X-rays are attributed to electrons moving at one half the velocity of light and emitting bremsstrahlung in the high atmosphere.

A balloon flight made from Fort Churchill, Manitoba, directed by Kinsey Anderson on August 29, 1957, has provided other remarkable evidence of the close interrelations of cosmic rays, soft radiation, and geomagnetic activity—although in this case no direct relationship with auroras was demonstrated. The balloon was instrumented with a vertical-counter telescope, a single counter, and a Neher-type ionization chamber.

A record of the data obtained is presented in Figure 3. The level at time A is the steady pre-storm cosmic-ray level; at B, soft radia-

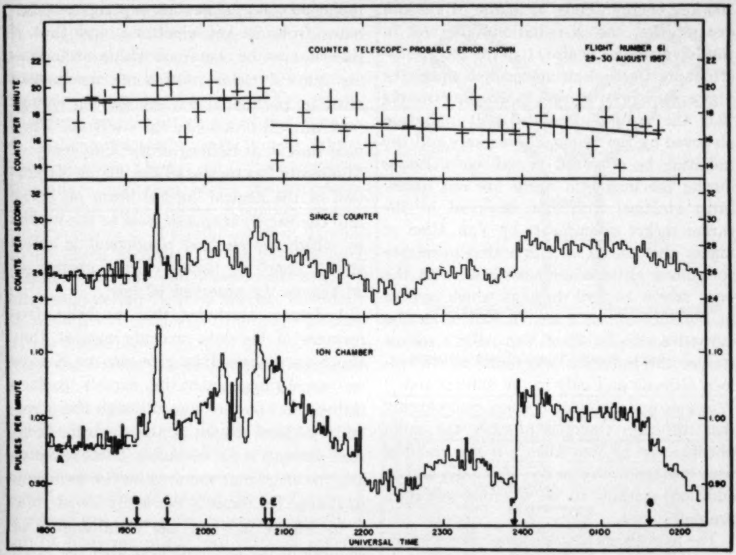

Fig. 3 Cosmic-ray and soft-radiation intensities over Ft. Churchill during the magnetic storm of August 29, 1957. (Reprinted from Journal of Geophysical Research, vol. 62, No. 4 [1957]).

tion begins to appear in both the single-counter and ionization-chamber records at the time when a magnetic storm commenced outside the auroral zone. The subsequent fluctuations of soft radiation, as shown by these records, were accompanied by a magnetic storm with changes in field as large as 400 or 500 gammas, beginning at Fort Churchill at time C. An intense burst of 30-mc radio noise was observed there at time D. An abrupt Forbush-type decrease depressed the counting rates of all these instruments after time E, but a very sharp increase in soft radiation took place at time F; it should be noted, however, that since the ionization chamber and single counter also count soft radiation, the drop at this time is not so apparent in them as in the counter telescope. It was accompanied by a large and rapid decrease of the vertical component of the earth's magnetic field observed at Fort Churchill. At time G, the sun set on the balloon, which began to sink rapidly. No unusual auroral activity was observed, except for a stationary region of low intensity on the evening of August 30, although a display of rayed bands was seen the following night.

The stopping power of the vertical counter telescope was less than that of the ionization chamber. Hence, incoming soft radiation in the form of charged particles should have been observed in it as well as in the other two instruments. It is therefore significant that no soft radiation was observed in the vertical counter telescope, and it was concluded that the soft radiation could only consist of X-rays with energies no greater than 700 kev.

Simulation experiments with X-ray sources at the State University of Iowa have shown that the relative response of the ionization chamber and single counter could be reproduced by X-rays of approximately

100 kev energy. Thus, as in the Minnesota experiments, the X-radiation observed in the Iowa studies is also attributed to bremsstrahlung from electrons incident upon the atmosphere from outside. Anderson remarks that the auroral-associated soft radiation observed by the Minnesota workers and the radiation he observed at balloon altitudes during the magnetic storm are not necessarily identical with that observed in the earlier rocket experiments by Van Allen at higher altitude. (The X-rays that penetrate to balloon altitude are associated with the very active auroral displays which appear in the sub-auroral zones as well as in the auroral zones. In all of Van Allen's rocket studies the radiation was found above balloon altitude and only in the auroral zone.) Winckler and Peterson concur, commenting that although theirs is possibly the same phenomenon as Van Allen's, it is correlated with visual auroras for the first time, and in addition appears to be a more energetic process.

The hypothesis that electrons are responsible for the creation of soft radiation raises the question of their origin. Winckler and Peterson favor the assumption that the soft radiation observed in their experiment originates from 60 kev electrons, and that if these cannot be contained within an incoming auroral beam itself some mechanism must be postulated for transferring energy from auroral protons to the electrons. They note that P. J. Kellogg of the University of Minnesota has suggested the charge separation of the neutral auroral beam on entry into the earth's magnetic field as the means by which the electron component is accelerated from its beam-velocity energy of 30 kev to the observed 60 kev.

Anderson concludes that at least two features of his data strongly suggest that electrons presumed to give rise to X-rays are accelerated near the earth's surface rather than on the sun, although the possibility of local release of the electrons from solar streams is not excluded. These features are: the short time required for the radiation to change its intensity markedly (as at time F in Figure 3), and the simultaneity of changes in the soft radiation with the large storm-type decreases in the earth's magnetic field.

Earth-Strain Measurements in South America

Two fused-quartz extensometers, relatively new instruments for measuring earth strain, have been installed at locations in the Andes Mountains as part of the US-IGY program in seismology. The project is directed by Hugo Benioff of the California Institute of Technology. The observing stations are operated by the University of Chile and the Peruvian National Committee for the IGY.

Standard seismometers, which have been used since the late 19th century, record ground motion during the passage of elastic waves, whose source may be either an earthquake or an artificial explosion. The extensometer, or strain seismometer, on the other hand, measures the differential motion between two nearby points (the ends of the extensometer). The change in the length of the extensometer, either increase or decrease, when divided by the original length, represents the change in strain.

The first extensometer employed for routine observations was designed and installed by Benioff more than 20 years ago. This instrument used an iron pipe as a length standard and a moving-coil-type electromechanical transducer. About 10 years ago, a redesigned version, using a fused-quartz rod as a length standard and a capacity bridge transducer, was installed at Isabella, California. The quartz rod greatly reduces undesirable variants caused by temperature fluctuations, and the capacity bridge increases the response of the extensometer to include waves of very low frequencies (or long periods). The South American extensometers are of this type.

The extensometers will provide three kinds of observational data: measurements of secular (long-range) strain changes occurring in the great Andes mountain range; measurements of the tidal (diurnal) strains of the earth produced by the gravitational action of the sun and moon; recordings of ultra-long-period seismic waves, including possible free vibrations of the earth excited by earthquakes.

Measurements of secular strains and their accumulation, made at an adequate number of stations over a long interval of time, may yield sufficient information to determine the strain pattern and habit of a region. It is conceivable that such knowledge might ultimately provide a basis for the prediction of earthquakes. The time required for such a study, however, might well run into several centuries.

Measurements of tidal strain provide information on the elastic and plastic properties of the outermost portion of the earth. The long-period waves yield information concerning the mantle and core of the earth as well as the mechanism of the generation of earthquakes.

One of the new extensometers is located at San Cristobal, in the outskirts of Santiago, Chile; the other is in Chosica, a small settlement some 20 miles from Lima, Peru. The University of Chile, at Santiago, and the Peruvian National Committee for IGY, at Chosica, have excavated the tunnels in which the instruments are located, are providing electric power at the sites, and are supplying personnel for the operation of the stations.

Cinna Lomnitz, a member of the staff at the University of Chile, is local scientific advisor for the Santiago work. J. A. Broggi, Chairman of the Peruvian National Committee for IGY, is the scientific advisor at Chosica.

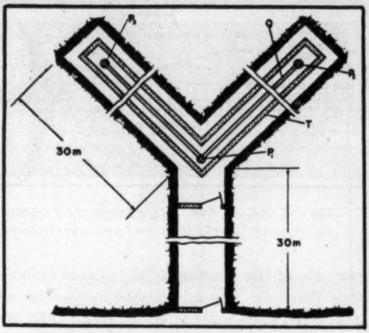

Fig. 4. *Schematic Plan View of the Extensometer Installation at Chosica, Peru.*

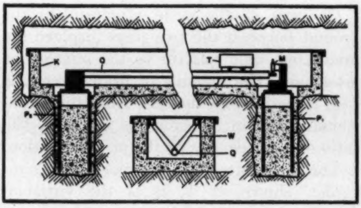

Fig. 5. *Schematic Vertical Section of One Extensometer Component.*

Each installation consists of two horizontal extensometers mounted at right angles in tunnels bored into igneous rock (see Fig. 4). The length standards are constructed of fused-quartz tubing with outside diameters of 2.5 inches, 0.25-inch walls, and lengths of 25 meters.

The mounting of the standards is shown above in a schematic vertical section through one component (Fig. 5). P_1 and P_2 are piers constructed of sections of 12-inch steel pipe sunk into the rock and cemented in with concrete. The quartz standard, Q, is rigidly fastened to one pier and is supported by a series of stainless steel wires, as shown by W in the inset. These prevent transverse movements of the quartz standards without exerting effective longitudinal constraints. Secular measurements are made with the measuring microscope, M, mounted on the

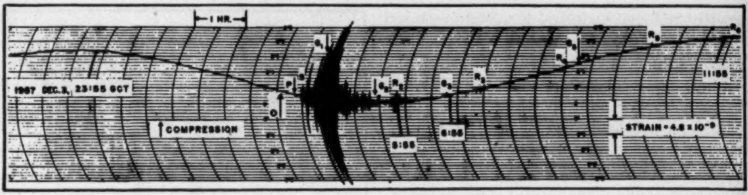

Fig. 6. *Record from Extensometer at Isabella, California. Vibrations set up by the Mongolian Earthquake (Δ = 10,000 km) are superimposed on the trace of the semidiurnal earth tide.*

pier, P_1, at the junction of the quartz standards (Fig. 4). The microscope focuses on a graduated glass scale mounted on the end of the quartz tube. (There are actually two microscopes at P_1, one for each quartz standard.)

Changes in the state of strain in the ground between the two piers displace the graduated scale relative to the microscope cross-hair. The amount of displacement is read directly from the scale, and the corresponding strain increment is given by the ratio of displacement to the pier separation.

The transducer for the tidal strain recorder, shown at T, is of the variable-capacity, resonant-bridge type and operates with a carrier frequency of 5 mc. It is constructed with transistors exclusively. Output from the transducer actuates the ink-writing recorder.

Fused quartz was chosen for the standards because of its low thermal expansion (about 5×10^{-7} per degree C) which, with the expected annual temperature variation within the tunnel of not more than one or two tenths of a degree, should permit secular strains to be measured with an accuracy of approximately one part in 10^7. However, since the diurnal temperature variation of the tunnel is very much smaller, tidal strains can actually be measured to within about one part in 10^9.

Recordings made with the extensometer tidal-strain recorder at Isabella, California, indicate that the sensitivity of the transducer recorder assembly is such that one division on the record represents a strain increment of 8.6×10^{-10}—equivalent to $\frac{1}{10}$ inch in 2000 mi. The South American tidal strain recorders are similar to this one in design and are expected to produce similar recordings.

Figure 6 is a record from the Isabella instrument showing the twelve-hour tidal period for December 4, 1957. Superimposed are the strains from the large (magnitude 8.5) Mongolian earthquake of the same date. The letters G and R on the record refer to Love- and Rayleigh-type seismic waves, respectively. These waves have travelled along the outermost portion of the earth's mantle, just beneath the relatively thin crust (10–50 km thick), from their earthquake source to the instrument site. Such waves travel outward from the disturbance in all directions, commonly circling the earth a number of times.

Love waves travelling the shortest arc to the instrument (10,500 km) are here designated G_1. Love waves travelling the longest arc (29,500 km) are designated G_2 and Rayleigh waves travelling the longest arc are designated R_2. The second passages of the short-arc waves are shown by G_3 and R_3, and of the long-arc waves by G_4 and R_4. Symbols representing subsequent passages have correspondingly higher subscripts. The time of origin of the quake is represented by 0. P and S indicate the first arrival of compressional and shear waves, respectively, which have penetrated the mantle to considerable depth.

Volunteer Satellite Tracking by Radio

The primary method employed in the US-IGY program for radio tracking of earth satellites is the Minitrack system described in *Bulletin No. 2, August 1957*. Two other tracking systems are also in use in a volunteer supporting program designated Moonbeam. One, a simplified version of the prime Minitrack system, is designated Minitrack Mark II. The other, developed by the Jet Propulsion Laboratory of the California Institute of Technology, is called Microlock. It is used in conjunction with the JPL receiving system. Like Minitrack, both Minitrack Mark II and Microlock use the interferometer principle (measurement of the phase difference of signals received simultaneously at different antennas) to determine the angular position of the satellite. The principle of angular position determination by interferometer measurement is explained in the report cited above.

Minitrack Mark II

The Minitrack Mark II is a relatively inexpensive system which can be built and installed with the resources available to many serious volunteer groups. The Mark II system in its simplest form is diagrammed in Figure 7. In this form, the Mark II provides only a meter indication of the presence and passage of the satellite.

This basic system can be modified to provide information accurate enough to be used in computing orbits. A block diagram of such a modified system is shown in Figure 8. When 1000-foot baselines are used and a precise time signal is recorded simultaneously with the interferometer data, this system can give time indications of satellite positions for approximately each quarter of a degree of satellite travel parallel to the base line.

Although the phase difference data recorded by the Minitrack Mark II system may give ambiguous positions, these ambiguities can be resolved at the Computing Center by reference to data gathered by prime Minitrack stations.

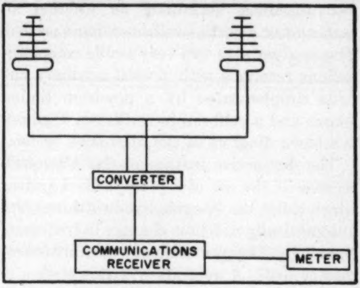

Fig. 7. *Simplest Form of Mark II Minitrack System.*

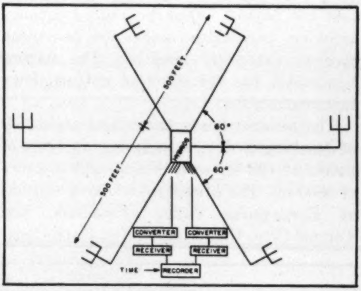

Fig. 8. *Advanced Mark II Minitrack System*

Minitrack Mark II stations are capable of tracking both the 10-milliwatt and the 60-milliwatt transmitters of 1958α to an accuracy of 45 seconds of arc and one millisecond in time. The 10-mw signal at 108.00 mc is preferred for accuracy in tracking, but the 60-mw signal at 108.03 mc is more easily received by most volunteer stations. To be of scientific value, a volunteer radio observation should be accurate to at least one milliradian, or 3½ minutes of arc.

Microlock

The Microlock system uses a variety of antenna arrangements. For the tracking of $1957\alpha2$ three antennas arranged in a right triangle were used. The antenna forming the vertex of the triangle is used as a common point in combination with either of the other two antennas, depending on whether an east-west or a north-south base line is needed. The receiver uses two very stable communications receivers with several auxiliary circuits supplemented by a precision timing source and a calibration oscillator. Figure 9 is a block diagram of the Microlock system.

The distinctive feature of the Microlock receiver is the use of a phase-locked system which shifts the 10-cycle bandwidth receiver automatically to follow changes in frequency caused by Doppler shift or transmitter-frequency drift. A byproduct of this system is an automatic recording of Doppler data. Figure 10 shows the basic phase-locked loop. The use of the phase-locked system and the narrow (10-cycle) radio-frequency tracking bandwidth makes the Microlock receiver extremely sensitive. The narrow bandwidth has the effect of cutting down extraneous noise.

The receiver has a theoretical capability of tracking a device radiating one mw of power at 108 mc at a line-of-sight distance of 3000 mi. The Microlock tracking stations at Earthquake Valley, Pasadena, and Temple City, California, and at Cape Canaveral, Florida, have tracked the 10-mw signal of 1958α at even greater distances.

The output of the tracking receiver and a time reference are fed into a pen recording trace from which the time of crossing of the meridian or parallel can be derived. Figure 11 shows a typical trace of a satellite passage.

The Microlock receiving system can also be used to receive 40-mc signals, one of the frequencies used by USSR satellites. To convert the system to reception of 40 mc, add a mixer to accept the 40-mc signals from the antenna. The communications receiver is then tuned to the difference frequency (2.3 mc) between the 40-mc signal and the output of the local oscillator (42.3 mc). With these changes the system will track the 40-mc satellite transmitter in the same manner as described above for the 108-mc transmitter.

Individuals and groups interested in participating in the Moonbeam volunteer radio tracking program may obtain information on the program by writing the National Academy of Sciences, IGY Earth Satellite Office, 2101 Constitution Ave., Washington 25, D. C.

Twentieth Award of the William Bowie Medal

Citation of Johannes Theodoor Thijsse

Prepared and Presented by WALTER H. BUCHER

This citation was to have been written and personally read by Hilding Beij, our former General Secretary who, as a hydrologist, is personally well acquainted with Professor Johannes Theodoor Thijsse and his work. To our deep regret, illness that led to an operation has made this impossible. When, as Chairman of the Committee, I was called upon to take his place, I turned to the letters in the Committee's files which help us in making final decisions. I shall quote primarily from a letter contributed at our request, at the time of our deliberations, by Prof. J. M. Burgers, at present of the Institute for Fluid Dynamics and Applied Mathematics at the University of Maryland, a former colleague and Professor Thijsse's fellow member of the Royal Netherlands Academy. You will find the main biographical data concerning the medalist in the brochure which you received at the entrance.

After obtaining his degree from the Delft Technical University in 1918, Thijsse became Executive Engineer of a Commission instituted by the Netherlands Government which was to investigate how far the closing of the Zuider Zee, Netherlands' shallow inland sea, would influence the height of the tides, especially the storm tides, on the coast of the province of Friesland. Here Thijsse worked in close cooperation with the Commission's president, H. A. Lorentz. This close cooperation with the famous theoretical physicist has been a decisive influence in Thijsse's scientific development.

Johannes Theodoor Thijsse
Recipient, Twentieth Award
William Bowie Medal, May 6, 1958

Lorentz succeeded in developing a method of calculation for the tidal motion in a network of shallow channels and basins, such as exist in the Zuider Zee and the waters between the Zuider Zee and the North Sea, where bottom traction is an important factor. This method took into account non-linear effects and was designed so that the influence of the wind could be taken into account. Thijsse carried through all the necessary measurements in the preparatory stage of the work and soon took part in working out the calculations. During the construction of the main dike closing in the Zuider Zee, Thijsse was constantly engaged in making further measurements, to check the predictions of the theory and to get further data.

This work did not only yield essential information concerning the effect of the main dike on the height of the storm tides on the Frisian coast, but gave at the same time most valuable information on what could be expected from the tidal motion while the construction was in progress.

Since then, the application of the methods of calculation developed by Lorentz and Thijsse and their coworkers has become a standing part of engineering practice in connection with reclamation projects and other constructive enterprises on The Netherlands coast and, in general, in those parts of river courses which are affected by tidal motion.

The vastly complex project of draining the Zuider Zee was based on model experiments carried out chiefly in Professor Rehbock's famous hydraulic laboratory in Karlsruhe, Germany. While the actual work was in progress, Thijsse was charged with the task of creating a hydraulic laboratory in The Netherlands in which to continue the model experimentation with which to direct the field projects. The laboratory was opened in 1927 in the basement of the Department of Civil Engineering of the Technical University at Delft, with Thijsse as its Director. Soon the amount of research to be carried out increased to such an extent that a separate building had to be erected which was opened in 1933. It was given a special form of management which made it formally independent of the Technical University while all scientific connections were maintained. In 1938, Thijsse was appointed part-time Professor of Theoretical and Experimental Hydraulics at the Technical University. In 1946, he was made full Professor. In 1948, he was elected a member of the Royal Netherlands Academy of Sciences.

In the many problems of hydraulics that have been studied in the laboratory, great care was always taken to treat fully the purely scientific side of each problem. He passed on to all who worked under him what he himself has called the chief lesson Lorentz had taught him: to approach every practical problem by digging back to the fundamentals of theory.

Among the problems investigated in the laboratory are those of influence of the wind on the water, especially the formation of waves; the action of waves, both in canals and in basins, with special attention to the problem of bed load and the various model ratios needed in experimentation; and, finally, the application of the basic knowledge gained to the protection of dikes and ports against heavy tides or swells. For such complex model experiments a special wind tunnel of large dimensions was constructed which has now been superseded by a still larger one that is under construction in the *Noort-oost Polder* near Vollenhave in the Netherlands, where open air facilities are available for making experiments with large amounts of water.

Thijsse's leading position in hydrology rests on these fundamental researches and their effective engineering application. The Bowie Medal honors an additional distinction; a breadth of interest and a consequent willingness to give of one's time and knowledge to colleagues working in other fields of science.

Thijsse's father was one of the important biologists of the Netherlands, who did much to promote a general interest in observational biology—an interest which our medalist has maintained all his life. It has influenced many a decision of the board for the reclamation of the Zuider Zee which he directed in the interests of biological ecology. To quote one characteristic action: Thijsse saw to it that filling material that had to be disposed of, was used to build an island designed to serve as a bird refuge.

Thijsse took an active interest in the geological and geophysical aspects of the changes in sea level that have followed the removal of the Pleistocene ice load from Scandinavia. Together with Professor Vening Meinesz and the late Professor Umbgrove, he has studied the detailed evidence produced by Pleistocene geologists of Scandinavia. Burgers wrote that since Thijsse became a member of the Royal Society, he was always to be found at the table where geologists, paleontologists, biologists, and members from other disciplines were collected, a group which Burgers frequently joined, and where Thijsse's opinions and advice were always eagerly sought.

Professor Martin Rutten wrote,"... as a council member of our Dutch geographical society, Thijsse has always made available his experimental work and his keen insight to geographers, pedologists, and geologists.... I remember well a stimulating lecture of his, given some four years ago, under the title of *The Map of Holland in the 21st Century*. In Toronto, last September, Thijsse agreed to go with geologists into the question of ebb and flood in the very wide, very shallow shelf seas such as must have been in existence in Mesozoic and Paleozoic times."

This breadth of vision and comprehension of the problems that men in other disciplines face is the criterion for the award of the Bowie Medal—designed to encourage "unselfish cooperation in research."

In 1952, Thijsse was invited to give a semester course at the University of Michigan—where Vening Meinesz, another Bowie Medalist, will give a semester's course next Spring. However, in February, 1953, he was called back telegraphically by The Netherlands Government to give his help in coping with the disasters brought about by the catastrophical sea surge and flood.

Since then, Thijsse has been in charge of much of the work that had to be done to repair the damage. Experience with the problems that confront the engineer in this field had been obtained already in closing the gaps in the dikes at Walcheren which had been made by the Allied Command near the end of the war in order to force the German troops out of the island. And again, in all this work, a difficult type of engineering work which requires the highest skill from all men involved, from captains as well as the personnel of dredges and tugboats, the guiding line of action was laid down by Thijsse—on the strength of his knowledge gained from his theoretical work and of the practical knowledge derived from the model experiments in his laboratory.

No wonder the Netherlands Government bestowed honors on him. For his share in dewatering Walcheren Island, he was made a Knight of the Netherlands Lion. Many other honors have come to him.

We honor him because as a leader in hydrologic physics and engineering he has maintained a wide perspective over many problems in other fields of science and stimulated thought and given advice to fellow workers in other disciplines. Mr. Vice President, it is a great privilege and pleasure to present to you Professor Johannes Theodoor Thijsse for the Bowie Medal.

Presentation

LLOYD V. BERKNER

Professor Doctor Engineer Johannes Theodoor Thijsse, by authority of the American Geophysical Union, and on behalf of President Ewing and the members of the American Geophysical Union, it gives me great honor and pleasure to convey to you the William Bowie Medal. This is the highest honor that we can award to our most distinguished colleagues.

Response and Acceptance, and Address: In the Borderland Between Geophysics and Engineering

J. TH. THIJSSE

It will be hardly necessary to say how grateful I am for the great honor which has been bestowed on me, especially to Dr. Berkner for the presentation of the William Bowie Medal and to Dr. Bucher for the citation.

I am sure that Dr. Berkner and Dr. Bucher will not mind when I declare that I am exceedingly sorry that the two persons whose names are printed in the program (President Maurice Ewing and K. Hilding Beij) and whose tasks they so graciously fulfilled, cannot be here tonight. Both Dr. Ewing and Mr. Beij are recovering from operations. You will agree with me that we all wish them to have a complete and speedy recovery.

Of course my achievements in geophysics have been exaggerated. Still I feel that, like several civil engineers in The Netherlands, I have done something in the line of oceanography and hydrology and that I have stimulated practical application of meteorology. I shall tell you how.

It takes a long time for an engineer to get familiar with geophysics. It is easier, however, if the engineer lives and works in a country which is so much affected by geophysical phenomena as The Netherlands, my home country.

The country is traversed by three rivers of some importance. One of them, the Rhine, carries the heaviest traffic in the world. The soil consists of thick layers of sand, clay, and peat, pervious to water. The surface of the land is slowly sinking in respect to the sea: at present great parts are situated below mean sea level. The consequence of this is that the ground water is brackish or salty and also that the country would be permanently flooded if the sea would not be kept out artificially.

The country is densely populated: six million dwell on six thousand square miles. These people have to live and, if possible, live in safety. The engineer has to see to that and the geophysicist helps the engineer in making his projects.

At the meeting of the International Association of Hydrology, IUGG, at Toronto in September 1957 I quoted an American meteorologist on the reaction of man on meteorological phenomena. I repeat it here, because I think it is true, not for meteorology only, but for geophysics in general. He stated that the first contact is in the realm of *superstition*. Later, from careful *observation* one finds an *explanation* of the phenomena. This may lead to *prediction* and eventually to *influencing*, which also may be called engineering. Superstition is not a subject for today; observation, explanation, and prediction are the work of the geophysicist, who leaves influencing to the engineers.

The tasks of the rivers is to carry their load of water, ice, silt, and sand safely to the sea and moreover to provide a continuous channel for navigation. In order to prevent flooding the ancient inhabitants built embankments, far enough apart and high enough to allow the maximum flood to pass. Hydrology did not yet exist at the time, so it could not give a definition of 'maximum flood.' Nevertheless the levees are in the places which we consider as correct at present. The question may be asked if our ancestors possessed a special instinct which guided them to this result.

After the levees were made the rivers did the usual thing, depositing silt on the floodlands every flood. Usually this leads to the consequence of raising the bed to an unacceptable level. No so in the case of Dutch rivers: the clay is dug away for the manufacturing of bricks, of which a stoneless country is greatly in need. Nor is there danger of raising of the main bed because the sand is dredged out and used for improving the stability of the soil where cities, roads, and airports are built, so navigation channels are maintained without extra cost. The rivers are in a good condition without the active help of geophysics.

It is different, however, in the case of the threat from the sea. This is influenced by the tides of the sea and its estuaries (oceanography), whipped to an extra high level by gales (meteorology). In the course of time the land has become lower and lower in respect to the sea level. Geodesists have to make observations on this phenomenon by successive accurate levelings. An explanation must be provided by studying the physics of the Earth's interior, by which also an attempt may be made at prediction.

It is now certain that the land has actually sunk and that the change has not been wholly due to rising of the sea level by recent melting of ice. Successive levelings have shown that tilting takes place: the northern part of the country is significantly lower than the southern part as compared with a century ago. The difference is about four inches.

Combining our observations with German and Scandinavian ones leads to the well-known theory that Scandinavia is still striving toward isostasy after losing its load of ice 20,000 years ago. The sima is being drawn from under the surrounding countries, the deepest depression being just north of Holland. Vening Meinesz, William Bowie Medalist in 1947, calculated the viscosity of the sima. There may be a complication by the 'melting' of the root under the Alps, but the effect of that is of minor importance. It is very probable that the rate of sinking, five inches per century in the south, nine in the north, is mainly caused by actual lowering; the rising of the sea level will be less than five inches per century.

On the strength of this, the prediction must be that the lowering will go on. The geologic effect will slow down, it is true, but only at a very small rate. This means that we must be prepared for higher sea surges than the present ones. A few inches every century does not sound very alarming, but in the long run it counts up. Twelve feet in two thousand years is a great deal; about the beginning of our era the surface of the land was high enough to be inhabitated without artificial means of defense against the sea. Prehistoric layers of peat, which are now situated far below sea level, can be accurately dated by means of the C^{14}

method, which shows that the average lowering during the past 70 centuries has been slightly more than the present rate.

The phenomenon is complicated by local compression of the soil and of the body of the levee itself. In some places the crest of the dikes sink an inch every few years.

This influences the defense system against the sea. Formerly each time the dikes were raised just enough to withstand a repetition of the last flood. Sometimes, when the economic position of the country was very good, they were raised a little bit more. After the gale of 1953, an attempt was made to find an economic optimum for the strength of the defense. Thus the principal man becomes the economist, who has to compare the cost of strengthening with the decreased risk of flooding. This cannot be done with any accuracy. Nobody knows the damage which will be brought about by a major flooding in the center of Holland. Also the frequency of very high floods is difficult to evaluate. There is a good record for 100 years and there are less reliable data extending over a period of six centuries. It appears that the optimum will be reached if the sea walls can withstand a gale and the consequent sea surge with a frequency of about 10^{-4} per year.

What is this level? Of course the statisticians have to provide an answer to that question, but they would be helpless without the aid of meteorologists and oceanographers. The trouble is that the data are not homogeneous; no two surges are alike. But rejecting part of the sample influences the extrapolation. I should like to have a thorough discussion on that subject at another time.

Instead of raising the embankment along the estuaries which penetrate deeply into the country, efforts are being made to shorten the coastline. The present stage is the Delta Project which plans to close five of these estuaries at their mouths. Previously we closed the Zuider Zee, banning the floods from the heart of Holland.

Operations like these greatly affect the tidal movement. At the beginning of the *Zuiderzeewerken* not very much was known about propagation of tides in shallow water. There were a number of observations, but the explanation was not satisfactory and so no prediction could be made as to the effect of influencing. Fortunately Lorentz, our greatest physicist since Huyghens, took charge of a panel of experts and indicated the methods which enables us to proceed with the work with eyes wide open.

In 1918 when the decision to enclose the Zuider Zee was made, it was not possible to construct the dam and the sluices therein in the actual coast line and a second line was selected, about 15 miles inland. New experience, mostly gained in the enclosure and in repair of dike breaks, together with progress of dredging and of auxiliary equipment plus a better knowledge of waves, permitted a bolder project: the Delta Project on which a start has been made recently. After completion, a second step may be made in the north by constructing dams through the gaps in the string of islands which is the actual coast of the North sea.

In many cases the last gaps have to be closed by floating a big concrete unit into place and sinking it. This may be a hazardous operation which can only be done in calm weather. In closing the last dike break after the 1953 flood a series of these operations had to be done in November, in the midst of the gale season. Our meteorologists found that there would be a calm period of sufficient length between two lows, crossing the Atlantic, Abraham and Charles, if the one between those two, Bernhard, would fade out. It did, and the operation was successful, but it was a great responsibility for our friends in the meteorological office in de Bilt.

These projects are multipurpose projects. They influence the economic life of whole regions and great care has to be taken that the result will be acceptable: the town and country planners are responsible for that.

The hydrologist is also involved, in several ways. Inside the enclosure dams, lakes come into being. After a few years the water in those lakes has been replaced by fresh water, which is used in time of drought in great areas around. Since 1937 the Yssel Lake, which is the former Zuider Zee, supplies fresh water to more than a million acres, where brackish water used to be plentiful, but where fresh water failed altogether.

The level of Yssel Lake has to be held to strict limits. It may not be so high that drainage of large areas would be effected; on the other hand there must be enough water for the needs. For the operation of the sluices in the enclosure, a fair knowlege of the future inflow is needed. Forecasting of rain is out of the question; fortunately most of the inflow comes from the Rhine.

The movement of flood waves down the Rhine is well known. The man in charge of the level of the lake knows several days in advance what he must expect and he tries to make room for an expected flood by evacuating as much water as possible. Long-term forecasting of the river flow is necessary in order to decide when to begin accumulating water for the summer months and to decide if rationing of water will be needed. (Up to now this has not been necessary.) In this respect we get great help from hydrologists of the Swiss Government, who use their snow surveys in forecasting river flow.
